ABA	Acid Base Accounting
ACT Labs	Activation Laboratories Ltd.
AEX Program	Advanced Exploration Program
AP	Acid Potential
ARD	Acid Rock Drainage
BV	Bureau Veritas
CarbNP	Carbonate Neutralization Potential
CarbNPR	Carbonate Neutralization Potential Ratio
CMR	Carbonate Molar Ratio
CND	Cyanide Destruction
CO_2	Carbon Dioxide
CVAA(S)	Cold Vapour Atomic Adsorption (Spectroscopy)
CVAFS	Cold Vapor Atomic Fluorescence Spectroscopy
DO	Dissolved Oxygen
EC	Electric Conductivity
EMPA	Electron Microprobe Analysis
FLB	Field Leach Barrel
Global ARD	Global ARD Testing Services Inc.
Great Bear Resources	Great Bear Resources Ltd.
H_2O_2	Hydrogen Peroxide
HCl	Hydrochloric Acid
$HClO_4$	Perchloric Acid
HDPE	High-density Polyethylene
HF	Hydrofluoric Acid
HNO_3	Nitric Acid
IC	Ion Chromatograph
ICP	Inductively Coupled Plasma
ICP-MS	Inductively Coupled Plasma Mass Spectrometry
ICP-OES	Inductively Coupled Plasma Optical Emission Spectrometry
ISE	Selective Ion Electrode
LOI	Loss on Ignition
MEND	Mine Environment Neutral Drainage
ML	Metal Leaching
ML / ARD	Metal Leaching / Acid Rock Drainage
MPA	Maximum Potential Acidity
Na_2CO_3	Sodium Carbonate
NAG	Net Acid Generation
NML	Non-Metal Leaching
NP	Neutralization Potential
NPAG	Non-Potentially Acid Generating
NPR	Neutralization Potential Ratio

ORP	Oxidation-Reduction Potential
PAG	Potentially Acid Generating
Project	Great Bear Project
PVC	Polyvinyl Chloride
PWQO	Provincial Water Quality Objectives
QA / QC	Quality Assurance / Quality Control
QEMSCAN	Quantitative Evaluation of Materials by Scanning Electron Microscopy
RPD	Relative Percent Difference
R-XRD	Rietveld X-Ray Diffraction
SFE	Shake Flask Extraction
SGS Lakefield	SGS Laboratories
SO_2	Sulphur Dioxide
TC	Total Carbon
TDS	Total Dissolved Solids
TIC	Total Inorganic Carbon
VMF	Viggo management facility
w/w	Weight / Weight
WAD	Weak Acid Dissociable
WSP	WSP Canada Inc.

UNITS

˚C	degrees Celsius
µm	micrometre
cm	centimetres
g	gram
kg	kilogram
kg $CaCO_3$/t	kilograms of calcium carbonate per tonne
km	kilometre
L	litre
m	metre
masl	metres above sea level
mg $CaCO_3$/L	milligrams of calcium carbonate per litre
mg $CaCO_3$/m^2/week	milligrams of calcium carbonate per square metre per week
mg/kg	milligrams per kilogram
mg/kg/week	milligram per kilogram per week
mg/L	milligram per litre
mg/m^2/week	milligram per square metre per week
mL	millilitre
mL/min	millilitre per minute
mm	millimetres
ng/L	nanograms per litre
nm	nanometres
wt.%	weight percent

ELEMENTS

Ag	Silver
Al	Aluminum
As	Arsenic
Au	Gold

1 INTRODUCTION

1.1 PROJECT BACKGROUND

Great Bear Resources Ltd. (Great Bear Resources), a wholly owned subsidiary of Kinross Gold Corporation, is proposing to develop a gold mine (the Great Bear Project). The Great Bear Project (the Project) is located approximately 25 km southeast of the Municipality of Red Lake (Figure 1.3-1) in northwestern Ontario.

This report has been prepared to describe the geochemical characteristics of geologic materials likely to be encountered (e.g., rock and overburden) or generated (e.g., tailings and, paste backfill) during mine development. This report documents the approach, methods, and results of the static and kinetic geochemical testing programs to assess the metal leaching and acid generation potential of Project materials.

For the purposes of this assessment, rock at the Project has been classified into two groups.

- Ore-grade materials: Samples collected from the open pit and underground mine volume that contained an economic gold content.
- Mine rock: All mine rock excluding ore-grade materials and including future exposed rock surfaces.

In addition to rock materials, tailings (generated from metallurgical test programs), paste backfill (generated from engineering test programs), and overburden materials were also tested as part of the Project geochemical assessment.

- Tailings: Tailings are a by-product from the processing of ore-grade material to recover gold. Geochemical testing included in this assessment utilized tailings samples generated from metallurgical test programs conducted for the Project. Current Project plans include the use of flotation to generate desulphurized tailings alongside a smaller volume of concentrate tailings.
- Paste backfill: Backfill will be generated for structural use in underground mining. Paste backfill, prepared from whole tailings, is currently planned to represent the primary form of backfill used at the Project. Geochemical testing of paste backfill utilized samples prepared according to current Project engineering specifications, using tailings generated from metallurgical programs.
- Overburden: Overburden represents the natural, unconsolidated materials overlying bedrock that will be excavated as part of Project development.

1.2 SCOPE OF WORK

This Geochemistry Summary Report summarizes the findings of geochemical baseline characterization work completed by WSP Canada Inc. (WSP) in support of the Project Impact Statement. Geochemical baseline studies comprised various programs and the data included in this report represents data collected up to July 2025.

The scope of the baseline program conducted for the Project has progressed over time based on ongoing development of the Project and subsequent technical findings of the geochemistry programs, plus feedback received from regulatory agencies and Indigenous communities. The metal leaching / acid rock drainage (ML / ARD) characterization program for the Project is highly robust and comprehensive. The magnitude of the collected dataset exceeds standard approaches for similar mining projects completed or undergoing the approvals processes in Ontario. Geochemistry investigations are continuing and will be reported during the environmental approvals process as appropriate.

Several comprehensive ML / ARD characterization programs were conducted to evaluate the geochemical characteristics of Project geologic materials, including:

- Static and kinetic testing of drill core samples, representing mine rock and ore-grade materials, including future stockpiled materials and exposed mine surfaces. Static testing included a program with 3,885 drill core samples from the mine volume. The kinetic testing program included 84 kinetic tests, with 35 humidity cell tests and 34 column tests operated in the laboratory, and 15 field leach barrel tests operated in the field at the Great Bear Property.
- Static and kinetic testing of metallurgical tailings samples including desulphurized tailings (seven samples) and concentrate tailings (nine samples) representing tailings to be generated under the current mine plan. Tailings testing was conducted on samples subject to bench scale cyanide destruction. Whole tailings (nine samples) were also tested, along with prepared paste backfill (one sample). Tailings kinetic testing included nine humidity cell tests and one column test. Two kinetic tests were conducted for paste backfill.
- Static and kinetic testing of overburden samples representative of overburden to be excavated as part of Project development. The static testing program included 172 overburden samples. Kinetic testing included 14 trickle leach column tests and six field cells which are under construction.

This report summarizes static and kinetic test data available to support the Impact Statement. Kinetic test programs continue to be routinely monitored. Targeted ongoing test work is underway to support mine engineering.

In addition to the above baseline geochemical data, the Project has an extensive exploration geochemistry database including multielement ICP data representing approximately 500,000 drill core samples within the mine volume which was used to develop ABA analogue relationships with the exploration geochemistry database. These relationships were utilized to generate an ML / ARD block model for the Project to support mine rock management.

1.3 REPORT STRUCTURE

This report contains relevant background and contextual information to guide the reader through key components of the Project geology (Section 2), the overall ML / ARD program design (Section 3), and analytical test methods used (Section 4). The static and kinetic testing programs for each geologic material characterized as part of the ML / ARD assessment are provided in the following sections:

- Section 5: Project rock, including mine rock and ore-grade materials.
- Section 6: Tailings, including desulphurized tailings, concentrate tailings and whole tailings, along with paste backfill.
- Section 7: Project overburden.

Appendix A provides information regarding analytical methods and detection limits used for the assessment.

Appendices B through N provide tabulated data and graphs related to the various test programs, as referenced throughout this document.

Certificates of analysis for the completed test work are provided in Appendix O.

2 PHYSIOGRAPHY AND GEOLOGY

2.1 PHYSIOGRAPHY

The regional topography includes low, rolling hills with numerous small lakes and spruce bogs. Project terrain is gently sloping with elevation ranging from 350 to 460 masl. Bedrock occurrences are rare on the property and, where observed, they are typically glacially polished. Overburden depth typically ranges from 1 to 20 m and averages 10 m.

2.2 GEOLOGY

The following geological information for the Project has been summarized from Great Bear Resources geologists and the Voluntary National Instrument 43-101 Technical Report (Pfieffer et al. 2023).

2.2.1 REGIONAL GEOLOGY

The Project is located within the Red Lake greenstone belt of the Uchi Subprovince of the Archean Superior Province of the Canadian Shield (Figure 2.2-1). The rocks of Red Lake greenstone belt (east trending) and Birch-Confederation greenstone belt (north trending) originated in a setting characterized by volcanic eruption and deposition of volcanic sedimentary sequences on an active continental margin, followed by subduction related arc volcanism and later continental collision causing metamorphism.

Gold mineralization within the Red Lake greenstone belt region is epigenetic and structurally controlled, manifesting in veins, lenses, fractures, and hinge zones along contacts between different geologic units.

2.2.2 PROJECT GEOLOGY

At a local scale, the Project area is bounded by intrusive batholiths within a northwest-southeast trending belt of metavolcanic and metasedimentary rocks that are interpreted to have been formed in a marine setting next to active volcanism prior to metamorphism.

The southwestern portion of the Property is within a mafic domain and consists of intercalated mafic volcanic flows, argillite, siltstone, iron formation, and minor local felsic volcanics (Figure 2.2-2). The mafic domain hosts two mineralized zones that together comprise only approximately 3% of the measured, indicated and inferred resources for the Project: the Limb Zone and Hinge Zone.

Gold mineralization in the Limb Zone occurs as silica-sulphide replacement alteration zones, including replacement of sediments if present, or as silica flooding and quartz-calcite veins in the absence of sediments. Gold mineralization in the Hinge Zone is present in quartz veins and is associated with weak carbonate quartz alteration.

At the center of the Property, a younger sequence of intermediate to mafic volcanic and volcaniclastic rocks are present, which have a similar stratigraphy, but higher proportion of felsic pyroclastic rocks compared to the western and eastern portions of the Property. These rocks host the greatest mineralization for the Project in the LP Zone, which trends northwest to southeast and contains disseminated gold hosted by felsic volcanics and volcaniclastic sediments. Alteration of the LP Zone is variable and includes strong to pervasive albitization and silicification of the felsic volcanic units, and sericite / muscovite alteration of the metasedimentary units.

Sulphide minerals including pyrite (FeS_2) and pyrrhotite (Fe_7S_8) are the main sulphides associated with gold mineralization in all three ore zones. Lesser arsenopyrite (FeAsS) and minor amounts of chalcopyrite ($CuFeS_2$), sphalerite (ZnS), and galena (PbS) have been observed to be associated with the mineralized zones.

The northeastern portion of the Property is characterized by a felsic domain consisting of porphyritic dacite flows and volcaniclastic rocks intercalated with sedimentary layers.

Figure 2.2-3 presents the stratigraphy at the property. The rock types and stratigraphy inferred from exploration drilling is consistent across the property. Table 2.2-1 summarizes key rock types from the current geological interpretation for the Project.

Current Project plans include the development of two open pits, LP Central pit and the Viggo pit, and an underground mine. The mine volume is generally situated within the LP Zone of the deposit. The Limb and Hinge Zone are intercepted by the underground mine volume but they represent a limited proportion of the overall mine volume for the Project.

Table 2.2-1: Key Rock Types

3 PROGRAM DESIGN

3.1 REGULATORY CONTEXT

The approach and testing methods used in this report are based on the requirements described under the Ontario *Mining Act*; namely guidance found within the reference document *Prediction Manual for Drainage* Chemistry *from Sulphidic Geologic Materials* (MEND 2009), which represents best practice and industry-standard approaches and methodologies for ML / ARD sampling and characterization in Canada.

3.2 OBJECTIVES AND APPROACH

The overall objective of the ML / ARD program is to establish the necessary data and knowledge to support environmental approvals, engineering design and management decisions for various geological materials including mine rock and ore-grade materials, tailings, backfill and overburden.

Specific objectives of the ML / ARD characterization program included:

- Accurate representation of the geochemical characteristics of geological materials (mine rock, ore-grade materials, tailings, paste backfill and overburden) proposed to be generated through comprehensive sampling, analytical testing and data analysis.
- Estimates of the weathering behaviour of the above-mentioned geological materials through geochemical testing and monitoring studies.

A substantial amount of data has been collected for the Great Bear Project, which includes 500,000 exploration assay samples and 3,885 drill core samples collected to support the geochemical studies referenced herein. Table 3.2-1 summarizes the geochemical testing conducted for the Project. Detailed information on each mine material is provided in the Sections listed in Table 3.2-1.

The following sections describe the purposes of each of the tests that were used. Detailed methodologies for the work completed are provided within this report.

Note: Abbreviations are provided in front of document.

3.3 STATIC TESTING

3.3.1 ACID BASE ACCOUNTING

The most common source of ARD is oxidation of sulphide bearing rock. The accepted approach for assessing future ARD risk is ABA. ABA is a group of analytical methods to assess the potential for a sample to generate acidity by determining the balance between acid producing (e.g., iron sulphides) and acid neutralizing (e.g., carbonates) minerals in a sample. This is measured by determining a neutralization potential and an acid generation potential of a sample through standardized testing and assumptions (MEND 2009).

Numerous minerals contribute to the acid neutralization capacity in a sample. Carbonate minerals (e.g., calcite and dolomite) are considered fast-reacting sources of neutralization capacity that weather fast enough to maintain neutral pH when sulphide oxidation rates are high. Aluminosilicate minerals are another source of neutralization capacity; however, they are typically only effective at neutralizing relatively low rates of acid generation and supplementing the acid neutralization by carbonate minerals. At high rates of acid generation aluminosilicates are typically not effective sources of neutralization capacity.

For samples with only Ca and Mg carbonate minerals (e.g., calcite and dolomite) present, CarbNP is a measure of the most readily available NP in a sample. CarbNP may overestimate available NP when Fe carbonates such as siderite and ankerite are present. The Fe carbonate minerals can be slower to react, and the Fe fractions of these minerals provide no net acid neutralization capacity under oxidizing conditions. Thus, careful interpretation of NP results is required. Identification of the type of carbonate minerals present can be supported by mineralogical analysis where necessary. CarbNP (i.e., NP provided by carbonate minerals) was used as the basis for the NP determination of a sample.

The oxidation of sulphur bearing minerals are the primary sources of acidity from sulphidic materials. Ubiquitous sulphide minerals including pyrite and pyrrhotite, along with other sulphide minerals, produce acidity when they undergo oxidation and contribute to the acid generation capacity of a sample. Some sulphide minerals, such as sphalerite and galena, do not produce acidity when they undergo oxidation by oxygen. As well, consideration of a sample's acid generation capacity included use of its MPA, which conservatively assumes that all sulphur bearing minerals in the sample generate acidity.

The ratio of NP to AP capacity is referred to as the NPR (NP/AP). NPR values are assessed on the criteria provided in Table 3.3-1, as identified in MEND (2009). NPR is a widely accepted criterion to characterize the potential of geologic materials to produce ARD. Values less than one indicate that the AP exceeds NP, and values greater than one indicate that a sample has excess NP. However, values of NPR between 1 and 2 are considered to have an uncertain acid generating potential, whereas NPR values greater than 2 are considered NPAG. An initial screening value separating PAG rock from NPAG is an NPR value of 2. A threshold value of 2 is generally accepted as industry best practice for rock and was utilized for current Project purposes for all tested samples.

CarbNP/MPA (or CarbNPR) is a similar measure to NPR but is based on the carbonate content of the sample and the total S concentration. In the absence of iron carbonates, this ratio generally provides a more conservative screening threshold between PAG and NPAG rock, by assuming the only available NP is from Ca and Mg carbonates and that all sulphur-bearing minerals generate acidity. If Fe carbonates are present, then this ratio may overestimate the effective CarbNP and lead to incorrect categorization of PAG rock.

NPR values were based on CarbNPR (CarbNP/MPA). Modified NP, AP, and NPR values were considered for supplemental purposes.

A complimentary approach to the ABA methods described above is to conduct other standardized tests, such as the NAG test which provides an assessment of the potential of a sample to generate acid (AMIRA 2002). The NAG test measures the final pH of a sample under enhanced sulphide oxidation by

the addition of hydrogen peroxide. Essentially, the test oxidizes all sulphide in the sample and measures whether there is sufficient neutralization capacity present to prevent acidic conditions in the sample. A final pH of less than 4.5 in this test is considered indicative of PAG material, whereas a NAG pH above 4.5 indicates a sample that has little potential to produce net acidity in the future and may be NPAG.

Sequential NAG testing, in which the sample is subjected to multiple rounds of oxidation with hydrogen peroxide were also conducted on samples when sulphide was not completely oxidized in the single addition NAG test. NAG test results were assessed in conjunction with the results of ABA testing.

3.3.2 ELEMENTAL CONTENT

An understanding of the minor and trace element concentrations of the material being assessed is important, since enhanced metal release and mobility is the primary concern of ARD. In addition, certain elements may also exhibit leaching under neutral drainage conditions.

Chemical digestion and analysis of a sample is used to quantify the concentrations of elements in samples but does not provide a direct assessment of metal leaching potential.

There are no regulatory standards that apply directly to the elemental content of materials in relation to metal leaching risks. In the absence of defined threshold values, the elemental content of the samples were qualitatively evaluated against average elemental continental crustal compositions (Price 1997). For screening purposes, samples with more than 10 times the average crustal abundance for a given element were considered to be enriched in that element and were given additional consideration in subsequent metal leaching tests.

Overburden samples were also screened against the Ontario Typical Range values for uncontaminated soils (MOE 2011). These comparisons were for initial screening purposes only and imply neither compliance nor non-compliance with soil quality standards.

3.3.3 SHORT-TERM LEACHING TESTS

The potential risk of short-term metal leaching was assessed by completion of empirical leach testing. Short-term leaching tests are used to screen samples for their metal leaching potential on a preliminary basis.

- SFE was used as an initial screening procedure on the short-term metal leaching potential of the samples. The test involves gently agitating a sample in deionized water at a ratio of 3:1 water to solids for 24 hours. SFE testing was conducted on a subset of rock samples selected to cover the major lithologies, with additional samples selected from minor lithologies, along with samples of tailings and overburden. Solid phase elemental content data were a key consideration in sample selection.
- Analysis of the leachate from the NAG pH test (described above) was also completed for a subset of drill core samples to identify potential parameters which may be of interest under net-acidic conditions. Selection of NAG leachate samples for analysis primarily focused on samples with acidic NAG pH leachate, but included other samples to cover a range of lithologies and solid phase metal contents were assessed. NAG leachate analysis provides only a total metal release under complete instantaneous oxidation of the sulphide content of a sample and should not be interpreted as a direct indicator of water quality. Sequential NAG leachate testing was completed as required on a subset of drill core samples, consistent with guidance in AMIRA (2002).
- Specifically for the tailings, water quality analysis of supernatant produced as part of metallurgical testing was also conducted. Supernatant samples were collected throughout various stages of tailings processing to provide information regarding process water that could be discharged with tailings during operations.

To provide a frame of reference for comparison purposes only, SFE and NAG leachate concentrations, as well as supernatant water quality data, were compared to Ontario PWQO for protection of aquatic life.

Screening of results in comparison to PWQO included the interim as well as prescribed (in place) values. PWQO guidelines, which are related to the pH, hardness, and alkalinity of receiving water, were based on the general chemistry of the receiving water. Parameters which were greater than their respective PWQO may be identified as parameters of potential interest in subsequent metal leaching studies (i.e., kinetic tests). However, it is recognized that leachate concentrations produced by empirical laboratory tests like the SFE and NAG test do not simulate actual drainage conditions. This comparison is strictly for reference purposes and implies neither compliance nor non-compliance with the specified standard or objective.

Kinetic testing, as described in Section 3.4 provides more detailed information on the metal leaching potential of a sample.

3.3.4 MINERALOGY

The mineralogy of a sample is fundamental to the understanding of metal leaching and acid generation potential. Mineralogical testing was conducted to support the overall ML / ARD assessment including interpretation of static test results and to assess the influence of sample mineralogy on the kinetic test results, including metal leaching potential and the lag times to net acidic conditions for PAG samples.

Bulk mineralogical analysis was conducted by X-ray diffraction with R-XRD on numerous samples of each rock type, along with tailings, backfill, and overburden. This technique provides a semi-quantitative to quantitative assessment of the mineral composition of a sample.

Detailed mineralogical studies including QEMSCAN and EMPA were also completed to assess major and minor mineral constituents and trace element content of those minerals at the micrometer scale.

Mineralogical data are used to improve the understanding of the forms and quantities of potentially acid generating and acid neutralizing minerals and the trace element content of minerals within the sample.

Table 3.3-1: ARD Classification Criteria

Classification (1)	Criteria	Interpretation
PAG	CarbNPR <1	Sample is likely to generate acidity
Uncertain	CarbNPR 1-2	Sample has uncertain acid generating potential
NPAG	CarbNPR >2	Sample is unlikely to generate acidity

Note:

1 Classification scheme based on MEND (2009) guidelines. For the purposes of this assessment, an NPR threshold of 2 was used to differentiate PAG and NPAG materials (see text).

3.4 KINETIC TESTING

Kinetic testing is undertaken to estimate the rates of weathering, oxidation and metal release in geologic materials. These tests can also be used to estimate the time to acid onset for PAG materials. There are no regulatory criteria that are directly applicable to assess metal release data from kinetic tests.

Kinetic testing can be done using laboratory tests under controlled conditions or using field tests at the Project site, which take advantage of actual site conditions (temperature, humidity, precipitation). These tests are completed on a carefully selected sub-set of samples and generally require operation over an extended time period with regular sampling and monitoring.

For the Project, kinetic testing programs included the following:

- Thirty-five mine rock humidity cells (63 to 109 weeks available data per test).
- Thirty-four mine rock trickle leach columns (26 weeks available data per test).
- Fifteen field leach barrels (approximately 1.5 years of monitoring data). The tests were prepared with drill core and are operated in the field at the Great Bear Project site.
- Nine tailings humidity cells (22 to 83 weeks available data per test) and one tailings subaqueous recirculating column (22 weeks available data). The tests were prepared with metallurgical test work tailings.
- Two kinetic tests for paste backfill, including one test operated as a subaerial test (25 weeks available data) and one test operated as subaqueous recirculating column test (22 weeks available data). The tests utilized prepared paste backfill.
- Fourteen overburden trickle leach columns (8 to 47 weeks available data per test). The tests were prepared with overburden samples from the Project.

The kinetic testing program for the Project was used to assess:

- Rates of sulphide oxidation, neutralization capacity depletion, and metal leaching.
- Interpreted timing to the onset of acidic conditions in PAG materials.
- Potential parameters of interest for metal leaching in Project materials.

Ongoing kinetic tests on selected rock and tailings samples are also being conducted to evaluate the applicability of potential Project-specific thresholds to distinguish PAG and NPAG materials.

3.4.1 LABORATORY KINETIC TESTS

The following sections describe the purpose and operation of various types of laboratory kinetic tests that have been used to characterize materials for the Project. Laboratory tests are small-scale tests, generally conducted with one kg (or several kg) of sample, as outlined below.

3.4.1.1 HUMIDITY CELLS

Humidity cells are a standardized laboratory test designed to estimate primary mineral reaction rates like sulphide oxidation and carbonate mineral dissolution over a long period of time.

Humidity cell tests involve placing a prepared sample into a Plexiglas column equipped with a basal drainage port and subjecting the sample to a weekly cycle of wetting and drying periods. In humidity cell tests, the size of the Plexiglas column, mass of the sample, volume of deionized water used, and the cycle of wet and dry days are standardized. The tests are designed to flush weathering products out of the cell so the rates of sulphide oxidation and NP release, along with metal release, can be measured. It is common for these tests to operate for several months or years.

A key use for the humidity cell data is to determine the rates of sulphide mineral oxidation and neutralization capacity mineral dissolution, in order to estimate the lag time to net acidic conditions for a PAG sample. Metal release rates are also determined and used to assess metal leaching potential. Humidity cell tests are a fundamental component of an ML / ARD assessment per guidance in MEND (2009).

3.4.1.2 COLUMN TESTS

Column tests are customized laboratory tests that are designed to provide information on drainage chemistry and release rates from a sample. Column tests are distinguished from humidity cells in that the column size, sample mass, sample grain size, ambient conditions and leachate volume can be customized to provide information in response to a specific objective for an ML / ARD assessment. Columns are also distinguished from humidity cells in that they generally operate with lower flushing rates to better simulate natural conditions which can result in incomplete flushing of secondary reaction products that form in the sample during oxidation.

Several types of column tests were used for the Project ML / ARD assessment, for a range of materials:

- Trickle leach columns were prepared with drill core samples to primarily evaluate neutral metal leaching from Project rock. The trickle leach columns involved placing a prepared (crushed) drill core sample into a Plexiglas column and leaching a set volume of deionized water through the sample on a weekly basis. Weekly leachates were collected and analyzed.
- Trickle leach columns were prepared with overburden samples to evaluate drainage quality from stockpiled overburden materials. The trickle leach columns involved placing an overburden sample into a Plexiglas column and leaching a set volume of deionized water through the sample on a weekly basis. Weekly leachates were collected and analyzed.
- A subaerial backfill test was prepared using a casted slab of paste backfill and trickling deionized water over the backfill surface each week, to evaluate metal release from paste backfill surfaces. Weekly leachates were collected and analyzed.
- Separate subaqueous recirculating columns were prepared for: a) sulphide concentrate tailings and b) paste backfill. In the subaqueous columns, the prepared sample was placed in the column, and a set volume of deionized water was maintained above the sample. For the sulphide concentrate tailings column, the overlying water was gently and continuously circulated over the sample. A sample of the overlying water was collected weekly and replaced with an equal volume of clean deionized water to maintain the water cover volume. For the paste backfill column, a peristaltic pump was used to recirculate deionized water from the bottom to the top of the column, and weekly leachate samples were collected from a port located at the base of the column. Subaqueous column tests provide insight into the reactivity of a sample stored under water.

3.4.2 FIELD KINETIC TESTS

Mine Rock Field Leach Barrels

FLBs were constructed at the Project site to gather information on field oxidation rates and drainage chemistry that is based on test operation under actual site conditions and at a larger scale than laboratory testing allows.

For each sample between 100 kg and 200 kg of drill core, each representing a single rock type, were placed into an open 205 L drum that was connected to a sealed sampling vessel through a basal drain and pipe. Precipitation was allowed to fall directly into the drum and flow through the contained sample material where it was then collected in the sample vessel for analysis.

Leachate samples from the FLBs were routinely collected and analyzed. Data were evaluated directly and compared to laboratory kinetic test results to inform the ML / ARD assessment.

Overburden Field Cells

Construction of overburden field leach tests are in progress. The tests will be conducted using large HDPE totes (approximately 4000 L) that are open to precipitation and fitted with a basal drain system connected to a sealed collection vessel. Each field test will contain 3 to 4 m^3 of overburden collected from six representative areas across the Project. Leachate samples from the tests will be routinely collected and analyzed. Data will be evaluated directly and compared to laboratory kinetic test results to inform the ML / ARD assessment. Operation of the tests is scheduled to commence in Fall 2025.

4 ANALYTICAL METHODS

4.1 OVERVIEW

Analytical methods utilized as part of the baseline geochemical characterization are described in the following section. This information is intended to provide a detailed description of test methods used as part of the ML / ARD assessment and to supplement the analytical method information provided in Sections 5, 6 and 7.

As indicated throughout this report, the methods utilized for the ML / ARD assessment are consistent with guidance outlined in MEND (2009), which represents best practice and industry-standard approaches and methodologies for ML / ARD characterization in Canada.

4.2 ANALYTICAL LABORATORIES

Laboratory programs and related analyses included in this report were carried out at commercial ML / ARD laboratories from 2022 to 2025, as described below.

- Static and kinetic testing of drill core, synthetic tailings, and overburden samples were conducted at:
  - Global ARD in Burnaby, British Columbia.
  - SGS in Lakefield, Ontario.
  - BV in Burnaby, British Columbia.
- Additional testing of drill core including 3,885 samples for S, TIC, and metals analysis were conducted at:
  - BV in Vancouver, British Columbia.
  - ACT Labs in Ancaster, Ontario.
- Leachates from field kinetic tests including the FLBs were analyzed at ALS, Winnipeg, and Manitoba.

A summary of analytical laboratories used for each program is provided in Table 4.2-1.

Multiple laboratories were used to support the varying needs of the analytical programs over time, and for quality assurance / quality control (QA / QC) checks to verify results (see Sections 5.2.4 and 7.2.4).

Table 4.2-1: Summary of Analytical Laboratories

Test Program	Static Testing	Kinetic Testing
Drill Core	Global ARD SGS Lakefield BV ACT Labs	SGS Lakefield
Tailings	Global ARD	Global ARD
Paste Backfill	Global ARD	Global ARD
Overburden	Global ARD SGS Lakefield BV	Global ARD
Mine Rock Field Test (FLB)	Global ARD SGS Lakefield	ALS Winnipeg
Overburden Field Cells	Global ARD	Under construction (Fall 2025)

4.3 STATIC TESTING METHODS

Static testing methods are described below. Methods are consistent with guidance outlined in MEND (2009).

4.3.1 SAMPLE PREPARATION

Drill Core

Samples were collected from drill core archived at the Great Bear Property. Samples were collected as half core, with some quarter core samples, depending on core availability. Sample collection procedures and approaches are discussed further in Section 5.2.2.

At the laboratory, drill core samples were initially crushed to <9.5 mm. A 1,000 g split was obtained for further preparation, and the remaining sample was archived for future test work. The 1,000 g split was crushed to <6.3 mm size.

- The 1,000 g split of <6.3 mm material was split into two representative samples, including a 250 g sample and a 750 g sample.
  - 750 g of the <6.3 mm material was crushed to 75% passing 2 mm, then pulverized to 85% passing 75 µm. Standard chromium-free ceramic pulverization bowls were used. The pulverized sample was used for ABA, elemental content analysis, NAG testing, and bulk mineralogical analysis (R-XRD).
  - 250 g of the <6.3 mm material was used for SFE testing.

Detailed mineralogical analysis was completed on a subset of drill core samples.

- Most samples were available as coarse rejects from the prep work described above. The coarse reject material represented a crush size of <9.5 mm or <6.3 mm for the mineralogy work; 150 g was further crushed to a P80 (80% passing) 150 µm for the polished section preparation for mineralogical analysis. A 0.2 to 0.5 g split was pulverized to 75 µm and was submitted for representative chemical analysis.
- For eight of the samples only pulverized (80% passing 75 µm) material was available for the mineralogy work. The preparation of polished sections and additional chemical analyses conducted as part of the program used the pulverized material directly.

Synthetic Tailings

Synthetic tailings samples were available from metallurgical test programs for the Project. The preparation of these samples as part of the metallurgical programs is discussed further in Section 6.2.2.

Prior to testing, all tailings samples were air-dried at room temperature, hand rolled (if required to break up samples) and split by riffling.

- A 150 g split of the samples was pulverized to 85% passing 200 mesh (75 µm) and used for ABA, NAG pH, NAG leachate, elemental content and bulk mineralogical analyses.
- A 250 g split of unpulverized sample was used for SFE testing where mass allowed. For some samples, limited mass was available, and a smaller split (minimum of 75 g) was used for modified SFE testing to retain enough sample mass for additional analyses.

Paste Backfill

Paste backfill was prepared according to engineering specifications for the Project as discussed in Section 6.2.2.

- Paste backfill was prepared at Global ARD in 2024 using whole tailings samples mixed with 3% (by dry weight) Terraflow binder.

- Water was added to achieve a solids content of 72.5% w/w, and the mixture was homogenized into a paste using a high-shear mixer.
- Paste backfill was cast in molds for testing and cured for 28 days at 35˚C, with relative humidity above 95% maintained throughout the curing period.

A 150 g split of the prepared backfill was pulverized to 85% passing 200 mesh (75 µm) and used for ABA, elemental content and bulk mineralogical analyses (R-XRD).

The remaining casted backfill was retained for additional test work.

Overburden

Overburden samples were collected as described in Section 7.2.2.

Overburden samples were air dried at room temperature and sieved to <6.3 mm size to remove coarse organic debris and oversized rock fragments. Testing was conducted on the <6.3 mm fraction. A 400 g split was obtained for further preparation, and the remaining sample was archived for future testwork.

- A 150 g split of the samples was pulverized to 85% passing 200 mesh (75 µm) and used for ABA, NAG pH, elemental content and bulk mineralogical analyses (R-XRD).
- A 250 g split of unpulverized sample was used for SFE testing where mass allowed. For some samples, limited mass was available and a smaller split (minimum of 40 g) was used for modified SFE testing to retain enough sample mass for additional analyses.

4.3.2 ACID BASE ACCOUNTING

ABA includes a number of complementary tests to assess the potential for a sample to generate acidity by determining the balance between acid producing and acid neutralizing minerals in a sample.

Analytical methods used for ABA analyses conducted on the samples as part of this assessment are described below.

Paste pH

Paste pH was used to assess the current balance of acidity / alkalinity in the samples. The paste pH is measured from the supernatant via a pH probe following mixing of deionized water[1] with pulverised sample to form a paste. Analysis of pH is useful for estimating weathering and leaching conditions and detecting samples with no reactive neutralizing minerals or a surplus of acidic soluble constituents. pH is a principal factor in both primary mineral reaction rates and secondary mineral solubility and therefore can have a large effect on drainage chemistry. Solid sample pH values are reported as paste pH and are measurements made on the mixtures of water and pulverized sample.

Forms of Sulphur and Acid Potential

Sulphur in a geologic sample can be represented in several forms, including sulphide, acid-leachable sulphate, acid-insoluble sulphate, organic S, and elemental S. ABA testing consisted of the analysis of total S, acid-leachable sulphate S, and sulphide S. S species were measured using the following methods:

- Total S was determined by Leco analyzer. Oxygen was passed over a pulverized sample as it was heated in an induction furnace. The SO_2 released from the heated samples was measured by an infrared sensor and converted to a S concentration based on the original mass of the sample.
- Acid-leachable sulphate S was determined by various analytical methods, as described below. Primarily, sulphate S was determined by HCl leach and Leco analyzer (Table A-1). A subset of samples were analyzed by HCl leach and turbidimeter, and sodium carbonate leach to verify the potential presence of insoluble sulphate minerals (Table A-1).

[1] Analytical grade deionized water used in all testing methods.

- Sulphate by HCl leach and Leco analyzer: A pulverized sample was digested with HCl at room temperature and washed with deionized water to remove any excess chloride remaining. The acid digested sample and an untreated sample are analyzed by Leco analyzer. The difference between the S measurements determined for the two samples represents the sulphate S content of a sample.
- Sulphate by HCl leach and turbidimeter: A pulverized sample was treated with HCl and boiled for 30 minutes. The digested sample was filtered, and the filtrate was analyzed by turbidimeter.
- Sulphate by Na_2CO_3 leach: A pulverised sample was mixed with Na_2CO_3. Deionized water was added and the mixture was boiled for 30 minutes. The digested sample was reconstituted with deionized water and filtered before HCl was added to reach a pH 7.0. The sample was submitted for sulphate analysis by turbidimeter. Coloured and / or turbid samples underwent additional preparation (e.g., filtering and treatment with hydroxylamine hydrochloride) prior to turbidimetric analysis.

- Sulphide S was determined by difference (i.e., total S minus sulphate S). Sulphide S by difference was utilized to represent the sulphide content for the majority of the samples, based on the assessment described in the sections that follow in this report.
- A subset of drill core and tailings samples also had sulphide S analyzed directly by HNO_3 leach, to supplement the determination of sulphide S by difference. For these analyses, a sample was first subjected to sulphate S analysis by hot HCl leach and turbidimeter, as described above. The solid residue remaining after filtration of the sample was treated with HNO_3 and sulphide was analyzed by turbidimeter. Samples that underwent sulphide S testing by HNO_3 leach are listed in Table A-1. Direct analysis of sulphide S is known to be influenced by several confounding factors as outlined in MEND (2009) and should be interpreted alongside other mineralogical information about the samples.

AP is a measure of a samples' potential to generate acidity from the oxidation of sulphide minerals. MPA is a more conservative term that assumes all S in a sample (sulphides and other S-bearing minerals) is available to generate acidity. For this work, MPA was calculated using total S. AP was also determined using the calculated sulphide S value (determined by the difference between total S and sulphate analyses).

Review of data for approximately 900 samples identified that total S aligned well with the sulphide content of the samples (e.g., S generally represented by sulphide S; see Section 5.2). Total S by Leco, as described above, was also highly consistent with S by acid digestion and ICP-MS analysis. Therefore, ICP-MS S measurements were used to calculate MPA values for samples where total S measurements by Leco furnace were unavailable (including partial ABA analyses for 2,504 samples).

Forms of Neutralization Potential

NP is a measure of the ability of a sample to neutralize acid. Two complimentary methods were used to assess the sample's NP; namely, the Modified Sobek method and measurement of carbonate C based on the analysis of TIC.

The Modified NP method measures the ability of the sample to neutralize a known volume of acid for a short exposure period.

- The amount and strength of HCl required for the Modified NP procedure is determined by the fizz test. The samples were ground to <0.24 mm (60 mesh), and HCl was added dropwise to 0.5 g of sample. The strength of the effervescence (fizz), which was determined by visual assessment, roughly corresponded to the content of reactive carbonates in the sample. Post-testing, fizz ratings were compared to the measured NP values as a QA / QC measure. Samples should not exceed the equivalent NP that is provided in Table 4.3-1.
- Modified NP was measured using the MEND (1991) method, which is an update to the 1989 Lawrence modified NP method. Pulverized samples were digested with a known amount of HCl determined based on the fizz rating assigned to the sample. After 24 hours, the residual acid was back titrated to a pH of 8.3, and the acid consumed by the sample was calculated in terms of calcium

carbonate equivalents. The Modified NP test via the 1991 MEND method is the most common Modified Sobek NP method utilized in Canada.

Measurement of TIC was used to determine CarbNP of the samples. TIC is assumed to represent the carbonate mineral content of the sample. TIC was primarily determined by HCl leach / Leco analyzer. The TIC content of some samples was determined by $HClO_4$ leach and coulometer. Confirmatory analysis utilizing both analytical methods was conducted on a subset of tailings and drill core samples for verification purposes.

- TIC by HCl leach / Leco: A pulverized sample was treated with HCl to allow inorganic carbonate species to effervesce as CO_2. The acid treated sample and an untreated sample are analyzed by Leco analyzer. The difference between the C measurements determined for the two samples represents the TIC content of a sample.
- $HClO_4$ leach / coulometer: A pulverized sample is placed in a glass bottle and purged with a CO_2-free carrier gas to remove atmospheric CO_2. The sample is acidified at 45 to 55˚C using $HClO_4$ and inorganic C species in the sample effervesce as CO_2 which is measured using absolute coulometric titration.

TC, including both organic and inorganic forms of C, was also analyzed as check against the TIC content (e.g., the TIC content should not exceed the TC determined for a sample). The TC content of samples was determined by Leco analyzer. Oxygen was passed over a pulverized sample as it was heated in an induction furnace. The CO_2 released from the heated samples was measured by an infrared sensor and converted to a C concentration based on the original mass of the sample.

4.3.3 NET ACID GENERATION TEST

Following completion of ABA and metals analysis, a subset of samples was tested by additional static testing methods including single-addition NAG testing outlined in AMIRA (2002) and summarized below. For some drill core samples with elevated sulphide contents (generally >1%S) sequential NAG testing was completed.

The NAG test is a complimentary test to ABA which provides an assessment of the potential of a sample to generate acid (AMIRA 2002). NAG tests use H_2O_2 to rapidly oxidize sulphide minerals in a sample and determine if a sample has enough neutralization capacity to buffer the acidity generated during sulphide oxidation. Approximately 2.5 g of pulverized sample was reacted with 250 mL of 15% H_2O_2 at room temperature until effervescence ceased. The sample was then heated for a minimum of two hours and boiled rapidly for several minutes to decompose the remaining peroxide. Deionized water was added to the sample volume to maintain a volume of 250 mL, and the pH of the resultant solution is determined by pH probe. This test will oxidize sulphides in concentrations of up to 1% S in the sample, higher sulphide contents may require an additional dose of H_2O_2 to completely oxidize the sulphide present.

In samples with >1% S, S may only be partially oxidized by a single addition of H_2O_2 and would be quickly neutralized by available neutralizing minerals. Sequential NAG tests can be utilized in this instance. The sequential NAG test is a multi-stage procedure. The steps of the single addition NAG test are carried out on the sample, the leachate is filtered and analyzed, and then the NAG test is repeated on the sample residue. The cycle is repeated until such time that there is no longer catalytic decomposition of the sample (i.e., when the NAG pH is >4.5).

4.3.4 ELEMENTAL CONTENT

An understanding of the minor and trace element characteristics of the rock mass being assessed is important as enhanced metal release and mobility is the primary concern of ARD. In addition, certain elements may also exhibit leaching under neutral drainage conditions.

Two chemical digestion methods were utilized as part of the ML / ARD assessment, including aqua regia digestion and four acid digestion. A description of each digest method and the objective of the test for the geochemical program are provided below.

Aqua Regia Digestion with ICP-MS

- Aqua regia digestion (e.g., a combination of HNO_3 and HCl) is considered a near total digestion for most minor and trace elements, since most minerals in the rocks are dissolved (including sulphides, carbonates, oxides, and sulphates), with the exception of some resistant minerals such as silicates that may only be partially digested. Dissolution of environmentally meaningful metal phases is generally achieved by this technique.
- Aqua regia digestion was conducted on rock, tailings and overburden samples after which the dissolved leachate samples were analyzed by ICP-MS scan for Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Ga, Ge, Hg, K, La, Li, Mg, Mn, Mo, Na, Ni, P, Pb, S, Sb, Sc, Se, Sn, Sr, Th, Ti, Tl, U, V, W, Y, Zn, Zr. Detection limits for each parameter are included in Appendix A (Table A-2).
- The results of the aqua regia digestion and ICP-MS scan were compared to qualitative screening values (e.g., 10 times crustal abundance) to evaluate elemental enrichment.

Four Acid Digestion with ICP-MS

- The four acid method (e.g., a mixture of HF, $HClO_4$, HNO_3 and HCl acids) is capable of dissolving most metal salts, carbonates, sulphides, silicates, sulphates and oxides, and provides a more complete breakdown of silicate minerals than can be achieved by aqua regia digestion.
- Chemical extraction by the four acid digestion was conducted on Project rock samples after which sample leachates were analyzed by ICP-MS scan for Ag, Al, As, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Ga, Ge, K, La, Li, Mg, Mn, Mo, Na, Ni, P, Pb, S, Sb, Sc, Se, Sn, Sr, Th, Ti, Tl, U, V, W, Y, Zn and Zr. Detection limits for each parameter are included in Appendix A (Table A-2).
- The four acid digestion may cause volatilization of some elements, including Hg and B, which may result in underreporting of these parameters. For this reason, Hg and B were not analyzed by the four acid method and aqua regia is considered a more suitable method for solid phase determination of these parameters.
- The four acid digest and ICP-MS scan was conducted to allow direct integration of the baseline ML / ARD characterization dataset with the Project exploration geochemistry database, which includes multielement ICP-MS data (by four acid digestion) representing approximately 500,000 drill core samples within the mine volume. Analyses conducted as part of the baseline assessment are being utilized to develop ABA analogue relationships with the exploration geochemistry database.

4.3.5 SHORT-TERM LEACHING TESTS

In addition to assessing metal leaching potential by identifying the risk of ARD, the risk of metal leaching has been further assessed by completion of empirical leach testing. This included SFE tests, NAG leachate analysis and tailings supernatant analysis. Of particular interest in short-term leach tests are any parameters that were identified as having an enriched solid phase elemental content (Section 4.3.4).

SFE testing (MEND 2009) was completed on a subset of drill core, tailings and overburden samples. NAG leachate testing (AMIRA 2002) was completed on a subset of drill core and tailings samples. Both tests were completed on samples representing a range of lithologies and elemental content values among the dataset. The NAG leachate samples were also specifically selected to represent samples that were classified as PAG by ABA testing.

Tailings supernatant (simulated process water from synthetic tailings) was also tested for its chemical composition. It is noted that supernatant samples collected reflect the laboratory bench-scale CND process and are not representative of the operational process. The use of data from these short-term leaching tests as an indicator of potential future process water quality is considered preliminary and holds no regulatory significance.

Shake Flask Extraction

SFE testing was used to assess the potential release of soluble metals during the initial stages of weathering. The SFE test was conducted on a 250 g split of sieved sample using a 3:1 deionized water to solid ratio. Where sample mass was limited, a smaller split of sample was used in testing (minimum of 40 g) and a 3:1 ratio of deionized water to solids was maintained. The samples were agitated for 24 hours. After agitation, samples were left to rest for one to three hours to allow suspended particles to settle before filtering through 0.45 µm filter paper.

Samples analyzed at Global ARD were agitated via a gyratory shaker. SGS Lakefield could not clearly confirm detailed method information regarding the agitation method used and it was unclear if the samples had undergone end over end shaking or were bottle rolled. As discussed in Sections 5.2.4 and 7.2.4, the shaking method used by SGS may have resulted in QA / QC issues with some specific samples which is discussed further in 7.2.4.

The filtered leachates were analyzed for pH, EC, acidity, alkalinity, sulphate, and dissolved metals (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, Zn and Zr). Additional parameters (e.g., total cyanide, WAD cyanide, free cyanide, total cyanate, thiocyanate, nitrate, nitrite and ammonia) were analyzed for the synthetic tailings samples. Analytical methods and detection limits for individual parameters are included in Table A-3 in Appendix A.

NAG Leachate

Analysis of the leachate from the NAG pH test described above was also completed to identify potential parameters which may be of interest for mine rock under net-acidic conditions. Sequential NAG tests were conducted as part of NAG leachate testing for samples with >1% S, consistent with AMIRA (2002). These results provide only an indicator of total metal release under complete oxidation of the sulphide content of a sample and should not be interpreted as a direct indicator of drainage water quality.

After a pulverised sample is reacted with H_2O_2 as part of NAG pH testing, the fully oxidized slurry is filtered through 0.45 µm paper and analyzed for pH, EC, acidity, alkalinity, sulphate, and dissolved metals (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, Zn and Zr). Analytical methods and detection limits for individual parameters are included in Table A-4 in Appendix A.

Tailings Supernatant

Tailings supernatant (simulated process water) was collected at various stages of metallurgical testing as described in Section 6.2.2.

Supernatant samples were shaken to homogenize and filtered through 0.45 µm paper. The filtrate was analyzed for pH, EC, acidity, alkalinity, sulphate, chloride, fluoride, nitrate, nitrite, ammonia, total cyanide, WAD cyanide, free cyanide, cyanate, thiocyanate, and metals (Ag, Al, As, B, Ba, Be, Ca, Cd, Co, Cr, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, W, Zn and Zr). Analytical methods and detection limits for individual parameters are included in Appendix A (Table A-5).

4.3.6 BULK MINERALOGY BY R-XRD

Mineralogy is fundamental to the understanding of metal leaching and acid generation potential of geologic materials. It is used to identify major and minor minerals, which can be used to improve the understanding of the forms of potentially acid generating and acid neutralizing minerals.

Bulk mineralogical analysis was conducted by R-XRD. This technique provides a semi-quantitative to quantitative assessment of the mineral composition of a sample.

Samples were ground to less than 10 µm and analyzed as a random powder mount using an X-ray diffractometer equipped with a step-scanning goniometer. The results reported represent the relative amounts of crystalline mineral phases in the mounted specimens normalized to 100%. This method is effective at identifying crystalline phases present in abundance greater than a few weight percent. With favorable peak profiles and minimal overlapping peaks, phases may be detected at less than one weight percent.

4.3.7 DETAILED MINERALOGY

Quantitative Minerology

QEMSCAN was completed on a subset of samples for quantitative mineralogy of major, minor and trace constituents, to further assess the metal leaching and acid generation potential of the samples in detail. QEMSCAN is configured to measure mineralogical variability based on chemistry at the micrometer-scale.

The QEMSCAN analysis utilized the following:

- Particle Mapping Analysis, a two-dimensional mapping procedure aimed at resolving liberation and locking characteristics of a generic set of particles. A predefined number of particles are mapped at a point spacing selected in order to spatially resolve and describe mineral textures and associations.
- Back scatter electron signal intensity, as well as an energy dispersive X-ray spectral signal at each measurement point. The assessment makes no simplification or assumption of homogeneity based on the BSE intensity. The spectral signal is used to assign mineral identities to each measurement point by comparing the spectrum against a mineral species identification program or database.
- The raw data collected by the instrument is extracted, reviewed for quality, and processed offline using the iExplorer software and reported in a standardized format. Processing includes textural and chemical refining of the data and classification into categories to extract appropriate mineralogical data for the program.

Additional details regarding the QEMSCAN analysis are described in Section 5.3.3.

Electron Microprobe Analysis

EMPA analysis was completed to determine trace element content of sulphide minerals. The trace element content of sulphide minerals can influence metal release rates and overall reactivity of some sulphides.

EMPA was conducted for target minerals identified in QEMSCAN analysis, using a JEOL JXA-8230 probe in point analysis mode with calibration to reference standards (Appendix C). Most samples underwent EMPA analysis for target minerals identified in QEMSCAN analysis. Some samples were not analyzed due to a low abundance of minerals of interest. Spot analysis targeted by the operator included quantification of the major elements for each mineral and selected minor elements. A lower limit of detection was determined for minor elements in the analyses using the 3-sigma method.

The sulphide and sulpharsenide minerals selected for analysis and the minor elements quantified for each are shown in Table 4.3-2.

Further EMPA analysis details are described in Section 5.3.3.

Geochemical Analysis

Geochemical analysis was conducted on the samples analyzed by detailed mineralogy. The geochemical analysis was completed to provide a reference and check on the element totals determined by QEMSCAN and associated element deportment totals. Analytical methods included:

- Total S and TC analysis by combustion using a C / S analyzer.
- Whole rock analysis of major elements by borate fusion X-ray Fluorescence.
- Four acid extraction of major and trace elements. Quantification was by ICP-OES for the first stage of work and ICP-MS for the second stage of analysis. Four acid digest was completed for quantification of total element content for comparison to QEMSCAN results.
- Aqua-regia extraction and quantification by ICP-MS was also included for the second stage of analyses for consistency with interim test work at the time and for completeness. Results were consistent and did not materially affect this study.

Whole rock analysis included quantification as major oxides: SiO_2, Al_2O_3, Fe_2O_3, MgO, CaO, Na_2O, K_2O, P_2O_5, MnO, TiO_2, Cr_2O_3, V_2O_5 and LOI. Four acid ICP-OES analysis included quantification of: As, Ag, Ba, Be, Bi, Cd, Co, Cu, Li, Mo, Ni, Pb, Sb, Se, Sn, Sr, Tl, Y, Zn. Aqua regia and four acid ICP-MS analysis included quantification of: Hg (aqua regia only), Ag, As, Al, Ba, B (aqua regia only), Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mn, Mo, Na, Ni, P, Pb, S, Sb, Se, Sn, Sr, Ti, Th, Tl, U, V, W, Y, Zn, and Zr. Hg and B were only provided by aqua regia digestion and ICP-MS since this lower temperature digestion allows Hg and B to be non-volatile under the analytical conditions.

Table 4.3-1: Acid Addition and Equivalent NP Values for the Fizz Test

Fizz Rating	Amount of HCl for NP Measurement (mL)	Normality of HCl	Equivalent NP (kg $CaCO_3$/t)
None / 1	20	0.1	50
Slight / 2	40	0.1	100
Moderate / 3	40	0.5	500
Strong / 4	80	0.5	1000

Table 4.3-2: Summary of EMPA Sulphide and Sulpharsenide Mineral Analysis

Mineral	Mineral Formula	Quantified Minor Elements	# of Analyses
Pyrite	FeS_2	Co, Ni, Cu, As, Se	603
Pyrrhotite	$Fe_{1-x}S$	Co, Ni, Cu, Se	431
Sphalerite	(Fe,Zn)S	Cd, Mn, Cu, Se	122
Arsenopyrite	FeAsS	Co, Ni, Sb, Se	77
Chalcopyrite	$CuFeS_2$	Co, Ni, Se	24
Galena	PbS	Se	31
Gersdorffite-Cobaltite	(Fe,Ni,Co)AsS	Sb, Se	24

4.4 LABORATORY KINETIC TESTS

Kinetic testing methods described below are based on guidance in MEND (2009). Kinetic tests are used to assess:

- Rates of sulphide oxidation, NP depletion and metal release.
- Interpreted timing of acid onset in PAG materials.
- Site-specific thresholds for use in defining PAG material, where applicable.

4.4.1 HUMIDITY CELL TESTING

Humidity cell tests were prepared with drill core and synthetic tailings samples following completion of static testing. The tests utilized 0.5 to 1.0 kg samples as described in Sections 5.4.2 and 6.3.3.

- Drill core samples were crushed to 80% passing 6.3 mm, homogenized and placed in standard mine rock humidity cells (10.16 cm inner diameter, 0.64 cm wall thickness). Humidity cell tests containing drill core samples operated under ambient conditions at the SGS Lakefield laboratory.
- Synthetic tailings samples were homogenized and placed in standard tailings humidity cells (20.32 cm inner diameter, 0.64 cm wall thickness). Humidity cells containing synthetic tailings samples operated under ambient conditions at the Global ARD laboratory.

Particle size analysis was conducted to verify the grain size distribution of the prepared drill core samples.

Each humidity cell test contains a perforated acrylic base plate located approximately 2.5 cm from the base of the column. Filter media was placed over the perforated disk to prevent fine particles from passing through. For the tests operated at the Global ARD laboratory, shark skin filter paper and a nylon

400-mesh screen were used, whereas the tests operated at the SGS Lakefield laboratory utilized geotextile fabric as filter media.

Prepared samples were carefully placed atop the base plate and arranged so the top surface of the sample was level. A port is located at the base of the column for sampling. Each column was covered with a 0.64 cm thick clear acrylic lid, which contained small holes through which deionized water was added and air was circulated. A conceptual diagram of a humidity cell is included in Figure 4.4-1. A photograph of tests operating at SGS Lakefield and Global ARD are included in Appendix A (Figure A-1).

Each humidity cell is operated on a weekly cycle, wherein the cell is exposed to humid air for three days followed by dry air for three days. On the final day of the cycle (day 7), the sample is rinsed with deionized water. The resultant leachate is collected from the sampling port at the bottom of the humidity cell and filtered through 0.45 µm filter paper prior to analysis.

Humidity cell leachates from rock samples were analyzed for pH, EC, acidity, alkalinity, sulphate, chloride, fluoride, dissolved metals (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, W, U, V, Zn, and Zr). In addition to the above, humidity cell leachates from tailings samples were also analyzed for nitrate, nitrite, total ammonia, total cyanide, WAD cyanide, free cyanide, total cyanate and thiocyanate. Ultra-trace Hg monitoring was initiated for mine rock leachate in May 2025 to provide Hg data reportable to an analytical detection limit of 0.00000004 mg/L. Analytical methods and detection limits for individual parameters are included in Table A-6.

Throughout testing, humidity cell results were monitored, and the frequency of analysis was adjusted based on the results observed, as described in Sections 5.4.2 and 6.3.1. In some tests for some parameters, where concentrations were consistently below detection limits, monitoring was discontinued after a period of time.

Leachate chemistry was used to calculate release rates:

- For humidity cell tests containing prepared drill core samples, release rates (expressed as $mg/m^2/week$) were based on estimated surface areas of the humidity cell samples. Grain size analysis was conducted on each test sample (Appendix D1). A simple geometric model of particle size and surface area (assuming spherical particles) was used to determine a reference surface area for each sample. For humidity cell tests containing synthetic tailings samples, release rates (expressed as mg/kg/week) were calculated based on the mass of the humidity cell samples.

Release rates observed over time were used to determine trends in metal release, the rates of sulphide oxidation and NP depletion, and to assess the acid generation potential of the samples, as described in Sections 5.4.2 and 6.3.1.

At the time of report preparation, no tests had been terminated and consequently no method information is provided on termination testing for the humidity cell test samples.

4.4.2 TRICKLE LEACH COLUMN TESTING

Trickle leach column testing has been completed for rock samples and is ongoing for overburden samples to assess drainage chemistry.

The selection of samples for column testing and specific objectives of trickle leach column testing for the various sample types are described in Section 5.5.2 and 7.3.2.

A conceptual drawing of a trickle leach column is shown in Figure 4.4-2, and photographs of the tests operated at SGS Lakefield and Global ARD are included in Appendix A (Figure A-2). Trickle leach column tests were prepared and conducted as described in the following sections.

Drill Core

Trickle leach columns were operated with prepared drill core at the SGS Lakefield laboratory under ambient conditions.

- Approximately 0.95 kg of homogenized, prepared drill core samples (crushed to <6.3 mm fraction) were placed into clear PVC columns (5.1 cm inner diameter, 33 cm height and 0.64 cm wall thickness). The resulting height of prepared sample in each column was approximately 26 cm.
- To allow the column to freely drain over the entire diameter, the base of each column was sealed with a 0.33 cm polypropylene perforated base plate fitted on top with a single sheet of needle punch geotextile.
- Columns were operated as subaerial trickle-leach columns where deionized water is passed through the sample at a steady rate representing simulated unsaturated porous flow in rock. Columns were flushed weekly with approximately 0.30 to 0.35 L of deionized water.
  - Deionized water was distributed using a manifold and drip irrigation emitters for columns COL-1 to COL-30. Flows and emitters were adjusted regularly to achieve the target flow (drip) rate in each column.
  - For columns COL-31 to COL-34 the deionized water was metered to each column using a peristaltic pump that had a 5:1 gear reducer and target flow rates were calibrated individually. A peristaltic pump was used for COL-31 to COL-34 with a gear reducer and a separate tunable cassette head for each column. Deionized water was fed from individual containers rather than a common source with the manifold.
- Each column set-up included an initial flushing procedure to remove any accumulated oxidation products present at test start-up that could influence test results.
  - The initial flushing procedure comprised one application of 0.25 L and two applications of 0.35 L of deionized water, for a total of 0.85 L passed through the column prior to weekly operation of the column.
  - Drainage from each flush was collected and analyzed to confirm leaching trends and that generally stable leachate concentrations were achieved after the second 0.35 L leach cycle. Concentrations measured after the second 0.35 L leach cycle were recorded as week 0 of the test.
- Dedicated clear 500 mL polyethylene terephthalate wide mouth bottles were used for sample collection with the sample vessels changed weekly. At vessel change, the samples were capped and submitted to the analytical lab for subsample preparation (preservation and filtration as required) and analysis.

Leachates were analyzed following each initial flush and then weekly for pH, EC, acidity, alkalinity, chloride, fluoride, sulphate, and dissolved metals (Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mn, Mo, Na, Ni, P, Pb, S, Sb, Se, Si, Sn, Sr, Th, Ti, Tl, U, V, W, Zn and Zr) for the duration of testing. Detection limits and methods used for analysis of individual parameters are included in Table A-6.

The column testing program included two blank columns. The blank columns were constructed in the same manner as the rest of the columns but operated in an empty state as a check on deionized water quality and any interactions with column materials as constructed.

The column tests were terminated after 26 weeks of operation.

Overburden

Overburden trickle leach columns were operated at the Global ARD laboratory under ambient conditions.

- Approximately 0.55 to 1.1 kg of homogenized overburden samples (sieved to <6.3 mm fraction) were placed into clear cast acrylic columns. The size of the column used for each test was selected based on the mass of sample available. A column height of 23 cm and wall thickness of 0.64 cm was used for all columns, and the inner diameter of columns ranged from 7.6 cm to 8.9 cm to achieve an approximate sample height of 10 cm.
- A perforated acrylic base plate, covered with shark skin filter paper and nylon 400-mesh screen, was located approximately 2.5 cm from the base. Each column was fitted with a 0.64 cm thick clear acrylic cover.

- Columns were operated as subaerial trickle-leach columns where deionized water was passed through the overburden sample at a steady rate, approximately representing precipitation flow into overburden. Deionized water was distributed through a trickle leach coil (showerhead type) placed at the top of each column. A peristaltic pump was used to push deionized water through the trickle leach coil to simulate rainfall over the surface of the sample. Two flow rates were used during testing to evaluate controls on leachate chemistry.
  - From week 1 to 14 (COL-1) and week 1 to 17 (COL-2 through COL-4), week 1 through 23 (COL-5), and the entire operating period thus far for COL-6 through COL-17 (8 to 12 weeks) a weekly flushing volume of 0.35 L deionized water was used. This was the minimum volume of water that could be passed through the column to guarantee a sufficient leachate volume to test all necessary parameters and to conduct reanalysis of leachate for QA / QC checks if required.
  - The weekly flushing volume was reduced to 0.18 L per week in week 15 (COL-1), week 18 (COL-2 through COL-4, and COL-6 through COL-17) and week 24 (COL-5), following the development of stable leachate conditions at the 0.35 L flushing volume.
- To achieve a pumping rate low enough to attain the prescribed weekly flushing volume, the peristaltic pump was operated on the following intermittent pumping two-minute schedule:
  - Weekly flushing volume of 0.35 L: 14 seconds on, 106 seconds off.
  - Weekly flushing volume of 0.18 L: 7 seconds on, 113 seconds off.
- Deionized water was allowed to percolate through the sample and the resultant leachate was collected from the base of the column on a weekly basis, filtered through 0.45 µm filter paper and analyzed for pH, EC, ORP, acidity, alkalinity, sulphate, chloride, fluoride, nitrate, nitrite, dissolved metals (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, W, Zn, and Zr). Analytical methods and detection limits for individual parameters are included in Table A-6.
- Ultra-trace Hg monitoring was initiated in May 2025 to provide Hg data reportable to an analytical detection limit of 0.00000004 mg/L. To facilitate this testing, monitoring of P (colourimetry) and Hg (CVAA) was discontinued to allow sufficient leachate for ultra-trace Hg analysis in the columns operating at the reduced flushing volume (COL-2 and COL-4; 0.18 L). Prior to discontinuing monitoring, both Hg and P had stabilized at concentrations below their respective analytical detection limit in COL-2 and COL-4 leachate.
- Three blank columns were included in the testing study. These columns were constructed in the same manner as the rest of the columns and operated in an empty state as a quality control check on deionized water quality and potential interactions with column materials or introduced contamination due to laboratory methods (i.e., filtering). The blank columns were analyzed for the same suite of parameters as the remaining columns.

At the time of report preparation, 12 out of the 14 tests continue to operate. The two columns that ceased operation became consolidated such that sufficient leachate could not pass through the sample.

4.4.3 SUBAQUEOUS RECIRCULATING COLUMN TESTING

Subaqueous recirculating column testing was conducted at Global ARD on a sample of synthetic concentrate tailings to assess sulphide oxidation and metal release under submerged conditions. As described in Section 6.3.1, one column test is currently in operation with synthetic concentrate tailings and 22 weeks of data are available. A conceptual drawing of the subaqueous recirculating column test is provided in Figure 4.4-3, and a photograph of the test is included in Appendix A (Figure A-3).

Prior to testing, synthetic concentrate samples were air dried and combined to achieve sufficient mass for column testing. Samples were thoroughly homogenized, and a representative split of the composited sample underwent static testing (ABA, elemental content by aqua regia and R-XRD) to characterize the material prior to kinetic testing.

The column was filled with concentrate tailings and deionized water as follows:

- Prepared concentrate tailings were carefully placed in a clear cast acrylic column (15.24 cm inner diameter, 56 cm height, 0.64 cm wall thickness). The base of the column was sealed and consisted of a perforated base plate covered in a shark skin filter paper and nylon 400-mesh screen. The mass of sample used was approximately 2.6 kg and reached a height of approximately 7 cm in the column.
- Deionized water was gently poured into the top of the column through a funnel to minimize disturbance to the sample. Approximately 3.8 L of water was added to saturate the concentrate sample and achieve an overlying water column of 21 cm for a liquid-to-solid ratio of 3:1 by volume.
- Tygon tubing was installed to operate the column and facilitate sampling:
  - A Tygon tube was positioned in the overlying water column 7 cm above the tailings - water interface and a peristaltic pump was attached to recirculate water above the sample surface at a rate of 0.5 mL/min.
  - Sampling was conducted via two Tygon tubes, one of which was installed at the tailings - water interface, and the other was installed 14 cm above the tailings - water interface. Individual leachate samples were drawn from each of the two sampling tubes weekly via peristaltic pump and were stored in nitrogen-purged bottles to prevent oxidation. After each sampling event, deionized water was added to replace the volume sampled in order to maintain an overlying water of 21 cm throughout the entire testing period.

Leachates were filtered through 0.45 µm filter paper and analyzed as follows:

- Leachate collected from the sampling tube located at the tailings - water interface was analyzed weekly for DO and ORP throughout the entire operating period of the test.
- Leachate collected from the sampling tube located 14 cm above the tailings - water interface was analyzed for pH, EC, ORP, DO, acidity, alkalinity, sulphate, chloride, fluoride, nitrate, nitrite, ammonia, total cyanide, WAD cyanide, and dissolved metals (Ag, Al, As, B, Ba, Be, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, W, V, Zn and Zr).
- Analysis was conducted weekly throughout the entire test period for all parameters except for nitrogen species (nitrite, nitrate and ammonia) and cyanide species (total cyanide and weak acid dissociable; WAD cyanide). Monitoring of these parameters was decreased to a biweekly frequency after stable low concentrations were observed in the first nine weeks of testing.
- Analytical methods and detection limits for individual parameters are included in Table A-6 in Appendix A.

Leachate chemistry was used to calculate release rates. Release rates were represented as a flux (e.g., release rate per planar surface area of tailings in contact with the overlying water column).

At the time of report preparation, the subaqueous recirculating column test on concentrate tailings continues to operate.

4.4.4 SUBAERIAL PASTE BACKFILL KINETIC TESTING

Kinetic testing of the paste backfill was conducted at Global ARD on a sample to assess sulphide oxidation and metal release in paste backfill under subaerial conditions (Section 6.3.1). The test was operated under ambient conditions for a period of 25 weeks. A conceptual drawing of the kinetic test is provided in Figure 4.4-4. A photograph of the test is provided in Appendix A (Figure A-4) for reference.

- Paste backfill was prepared as described in Section 6.2.2 and cast in a slab (50 cm length, 10 cm width and 2.5 cm thickness). A planar slab was utilized to represent a surface of paste backfill over which contact water could flow.
- The slab was placed in a custom clear acrylic mount (0.64 wall thickness) that had been built with a slight inclination (12.5 to 14 degrees) to encourage drainage down gradient.

- A perforated Tygon tube was placed perpendicular to the top of the slab to facilitate slow percolation of a uniform flow of deionized water across the paste backfill. Silicon barriers were placed along the slab edges to direct water flow downwards over the surface of the paste backfill slab.
- The test was operated at a flow rate of 0.35 L per week. This was achieved via an intermittent deionized water pumping system at a rate of 0.35 mL/min (on for 2 seconds, off for 18 seconds). The pumping rate was chosen to achieve the minimum volume of leachate required for the analytical testing suite (approximately 0.35 L).
- An initial flushing volume of 0.7 L was used to initiate the test to remove any accumulated oxidation products or curing residues. Leachate from this flush was collected, analyzed and recorded as week 0 of the test. Subsequent weeks maintained a consistent flushing volume of 0.35 L per week. A total of 9.45 L of deionized water was percolated over the paste backfill throughout the 25-week testing period.
- Leachate was collected at the base of the test mount on a weekly basis, filtered through 0.45 µm filter paper and stored in nitrogen-purged bottles to prevent oxidation. Leachate was analyzed for pH, EC, acidity, alkalinity, ORP, DO, sulphate, chloride, fluoride, nitrate, nitrite, ammonia, total cyanide, WAD cyanide, dissolved metals (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, W, Zn, and Zr). Analytical methods and detection limits for individual parameters are included in Table A-6.

Leachate chemistry from the subaerial paste backfill test was used to calculate release rates. Release rates (expressed as $mg/m^2/week$) were calculated based on the planar surface area of the backfill slab in contact with deionized water throughout testing.

The subaerial paste backfill test was terminated after 25 weeks of operation.

4.4.5 SUBAQUEOUS PASTE BACKFILL KINETIC TESTING

Kinetic testing of the paste backfill was conducted at Global ARD to assess sulphide oxidation and metal release in paste backfill under subaqueous conditions. The test was operated under ambient conditions for a period of 22 weeks (Section 6.3.1). A conceptual drawing of the subaqueous kinetic test is provided in Figure 4.4-5. A photograph of the test is provided in Appendix A (Figure A-5) for reference.

- Paste backfill was prepared as described in Section 6.2.2. For the subaqueous test, the paste was cast in spheres with a diameter of 2.5 cm. Each sphere was formed by casting two separate hemispheres, which were cured then secured together with a small amount of the prepared paste backfill mixture. A total of 162 spheres were prepared.
- The spheres were carefully placed in a clear acrylic column (15.24 cm inner diameter, 83 cm height and 0.64 cm wall thickness) atop a perforated acrylic base covered with a shark skin filter paper and nylon 400-mesh screen to reach a sample height of approximately 15 cm. The top of the column was capped with a 0.64 cm thick clear acrylic cover.
- Deionized water was gently poured into the top of the column using a funnel. Nine pre-leaching cycles (week -8 through week 0) were completed prior to initiating the subaqueous column test to remove curing by-products or soluble phases. This was conducted to simulate backfill that had been exposed to contact water prior to flooding.
    - In the first pre leach cycle, approximately 2.3 L of deionized water was added to saturate the spheres and obtain an overlying water column with a height of 5 cm water overlying the spheres. After 24 hours, the water was drained through the port located at the bottom of the column. Deionized water was added back to the column to reach an overlying water column of 5 cm (approximately 2.1 L in subsequent pre-leach cycles). A total of nine pre-leach cycles were conducted, amounting to a total volume of approximately 19 L passed through the material prior to the start of the test.
    - Leachate from each pre-leach cycle was collected and analyzed for pH, EC, TDS, sulphate, Al, Sb, As, Be, B, Cd, Ca, Cr, Co, Cu, Fe, Pb, Mg, Hg, Mo, Ni, P, K, Se, Ag, Na, Sr, S, Tl, W, U, V,

Zn and Zr. Results from pre-leach cycles were monitored to confirm that stored oxidation products or curing by-products had been flushed from the paste backfill. The kinetic testing was initiated when monitored parameters reached relatively stable conditions.

  - The spheres of casted paste backfill were fragile, and approximately half of the spheres broke into separate hemispheres as the deionized water was added in the pre-leaching cycles. This was accounted for as part of estimates of leachable surface area of backfill present in the column.

- After the pre-leaching cycles were completed, the column was drained and deionized water was added to reach a height of 47.5 cm over the spheres (approximately 9.1 L). The ratio of water to solids used in laboratory testing was established to be a reasonable approximation of the estimated water to rock ratio in a water-filled backfilled stope. A peristaltic pump was used to recirculate deionized water from the bottom to the top of the column at a rate of approximately one contact water volume per week (approximately 13.1 L, including pore volume and overlying water).
- Weekly leachate samples were collected from a port located at the base of the column and stored in nitrogen purged bottles to prevent oxidation. After each sampling event an equivalent amount of deionized water (e.g., 0.35 L) was added to the top of the column to maintain an overlying water column of 47.5 cm throughout testing.
- Leachates were filtered through 0.45 µm filter paper and analyzed for pH, EC, acidity, alkalinity, ORP, DO, sulphate, chloride, fluoride, nitrate, nitrite, ammonia, total cyanide, WAD cyanide, and dissolved metals (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, W, Zn, and Zr). Analytical methods and detection limits for individual parameters are included in Table A-6.

Leachate chemistry from the recirculating column test was used to calculate release rates. Release rates were represented as a flux (e.g., release rate per surface area of material in contact with the overlying water column). As previously mentioned, approximately half of the hemispheres separated when deionized was introduced in the pre-leaching cycles. For calculation of release rates, the surface area of paste backfill in contact with water was therefore determined based on 81 spheres and 162 hemispheres. Calculated release rates were used to assess trends in metal release under submerged conditions.

The subaqueous paste backfill test was terminated after 22 weeks of operation.

4.5 FIELD KINETIC TESTS

4.5.1 FIELD LEACH BARRELS

Field kinetic testing, consisting of FLBs containing drill core samples, was conducted to evaluate field-scale acid generation potential and metal release. Fifteen FLBs containing drill core and one blank FLB test are currently in operation and data from 20 sampling events are available (Section 5.6). A conceptual drawing of an FLB test is provided in Figure 4.5-1, and a photograph of an FLB is included in Appendix A (Figure A-6).

- Samples were selected as per the criteria described in Section 5.6.2. Selected samples were inspected prior to use in FLB testing and representative subsamples (10 to 14 per barrel) were collected for ML / ARD verification testing to confirm the geochemical properties of each test sample, including ABA and elemental content analyses.
- The FLB tests were constructed in an open area, away from regular site traffic and any overhanging structures that would impede precipitation.
- The FLBs were constructed using open-top plastic 250 L drums. A hole was drilled in the base of the drum and fitted with a PVC bulkhead fitting and straight PVC hose connection fitting. A filtration bed comprising quartz sand and geotextile was placed in the bottom of the barrel. A sealed leachate collection pail was constructed and connected to the drum with clear vinyl tubing and PVC fittings. The FLBs were constructed on an elevated platform with covered access for the leachate collection pails.
- Following the addition of filter sand, selected drill core was carefully added to the barrel. The mass of drill core added to each FLB varied between approximately 100 to 200 kg. A blank test was also included in the field testing program. The blank was constructed in the same manner as the rest of the FLBs but contained only the filter media (quartz sand) used in the tests.
- Leachate sampling was conducted bi-weekly by Great Bear Resources, from July to October 2023 and April to October 2024, totaling 20 sampling events (Section 5.6.3). Leachates were collected during spring to fall conditions in 2023 and 2024, but not during periods of ice buildup or when insufficient water was available due to dry weather.
- Throughout testing, precipitation data collected from the site's weather station was monitored and compared to the leachate volumes recovered from the tests to validate the performance of the FLBs. All FLB tests functioned properly, with no leaks observed or adjustments required during the monitoring period.

FLB leachates were analyzed for the following parameters. The order of parameters listed was established as the priority for sample collection, in the event of low volumes in leachate pails (that may occur during periods of low precipitation):

- Field parameters (temperature, pH, conductivity).
- Dissolved Hg.
- Dissolved metals (Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mn, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Ti, Tl, U, V, W, Zn, and Zr).
- General chemistry: anions by IC (sulphate, Cl, F), alkalinity, lab pH and conductivity.
- Total P.
- Acidity.
- TDS.

Analytical methods and detection limits for individual parameters are included in Table A-6 in Appendix A.

At each sampling event, field conditions (including weather and the collected leachate volume in the pails) were recorded, the pail was carefully moved from the barrel. If the pail contained greater than 2 L of leachate, sampling proceeded as follows:

- The sampler donned a clean pair of single-use powder free nitrile gloves.
- Leachate samples were drawn from the pail using a plastic syringe, taking care not to hit the sides of the pail. Leachate was placed in a field measurement cup / bottle (that was rinsed three times with leachate prior to use) and field parameters were recorded by a calibrated field meter that was rinsed with deionized water prior to use.
- A new plastic syringe was rinsed three times with leachate and used to collect water quality samples as described below:
  - Unfiltered samples (pH, acidity, alkalinity, conductivity, total P, anions and TDS) were collected first. If the sample bottle did not contain preservatives, the bottle was rinsed three times with leachate prior to collecting the sample. If the sample bottle contained pre-loaded preservatives, the sample was added directly to the bottle without rinsing.
  - Filtered samples (Hg and metals) were collected subsequently. The syringe was used to collect leachate from the pails as described previously. Before discharging to a sample bottle, a 0.45 µm field filter was affixed to the end of the syringe. A few mL of leachate was dispensed through the filter to rinse the membrane, and the remaining leachate was dispensed into sample bottles. When the syringe was emptied, the filter was removed and held by the edges while the syringe collected additional leachate from the pails. The filter was reattached, and leachate was dispensed until all the sample bottles were full. Multiple filters were used while sampling as required.

If a pail contained less than 2 L of leachate, sampling was conducted as described below:

- The sampler donned a clean pair of single-use powder free nitrile gloves.
- A new plastic syringe was rinsed three times with leachate and used to collect water quality samples:
  - Filtered samples (Hg and metals) were collected first. Field filtering and collection of samples was conducted as described above.
  - Sampling was continued according to the priority list of parameters presented above, following sampling procedures described for unfiltered samples and field parameters.

At each sampling event, one duplicate sample and one field blank containing lab-supplied deionized water was also collected. The duplicate sample was analyzed for the same set of parameters as the FLBs. The field blank was analyzed for dissolved metals and dissolved Hg.

In addition to the 15 FLBs, 1 blank FLB test (FLB-B) was included in the testing program. The FLB was constructed in the same manner as the rest of the tests but operated in an empty state to assess background conditions of the test. Leachate samples from FLB-B were measured for the same parameters as FLBs containing drill core.

Prior to shipment, samples were stored under refrigerated conditions (refrigerator or cooler). Samples were shipped under chain of custody directly from the Great Bear Property to ALS Winnipeg. Sample shipments were timed such that no parameters exceeded recommended hold times with the exception of pH, which has a hold time of 15 mins. Field pH measurements were taken to account for this known short hold time.

Release rates (expressed in mg/kg/week) were calculated based on the mass of drill core used in each FLB test and used to assess sulphide oxidation and metal release under field conditions, as described in Section 5.6.

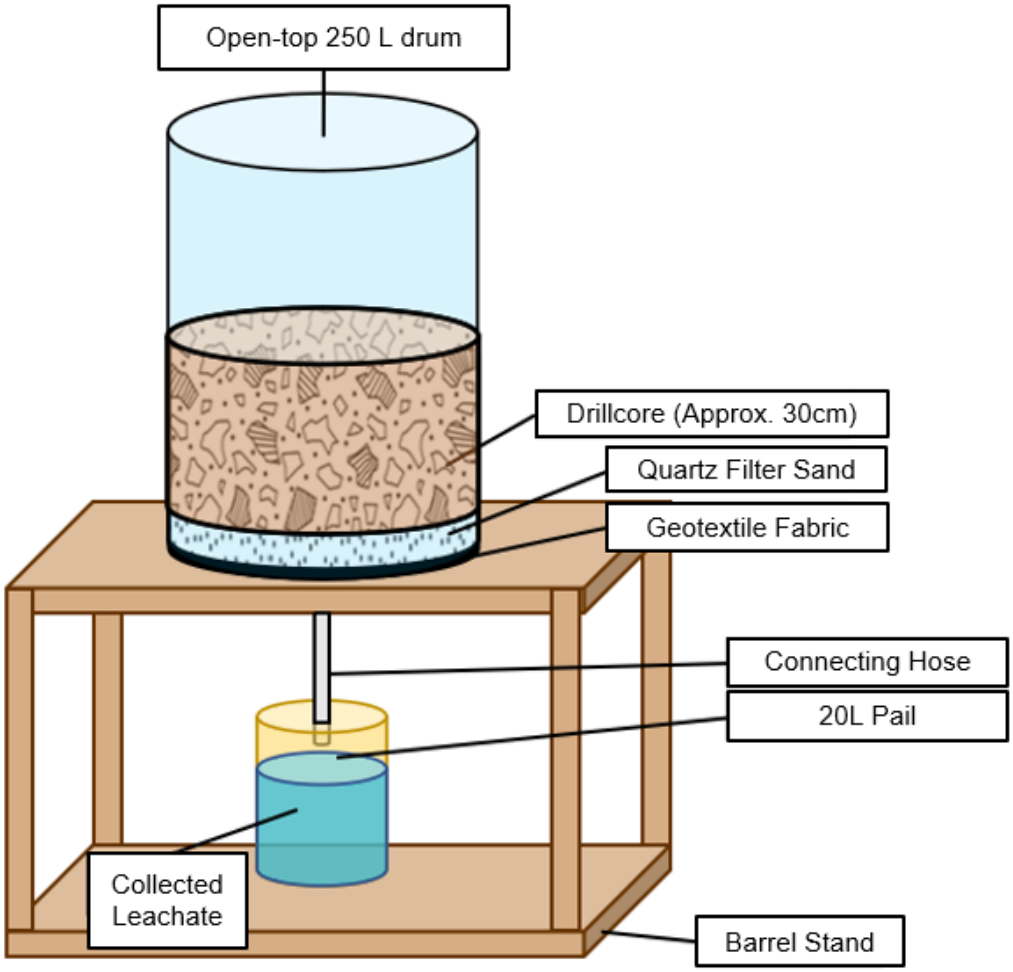

Figure 4.5-1: Conceptual Drawing of a Field Leach Barrel Test

4.5.2 OVERBURDEN FIELD LEACH TESTS

Construction of overburden field leach tests is underway to evaluate field-scale acid generation potential and metal release. Six field leach tests containing representative samples of overburden are planned to be constructed using 4000 L HDPE totes. A conceptual drawing of the field test is provided in Figure 4.5-2.

- Samples were selected to encompass the spatial distribution of overburden from across the Great Bear Project. Representative subsamples from each of the 3 to 4 m^3 test samples were collected for ML / ARD testing to confirm geochemical properties of each sample.
- The tests will be operated in an open area on site, away from routine site traffic and overhanging structures or foliage that would shelter the field test from precipitation.
- The HDPE totes will be equipped with a basal drain and will be mounted on a platform at a slight angle to facilitate drainage through the basal drain. A quartz sand filtration bed and geotextile liner will be added to the bottom of the tote, which will be connected to a sealed leachate collection pail with clear vinyl tubing and PVC fittings.
- Following addition of the filter sand, the 3 to 4 m^3 overburden sample will be added to the tote.
- Leachate sampling is planned to be conducted bi-weekly by Great Bear Resources in tandem with sampling from the FLBs as described above.

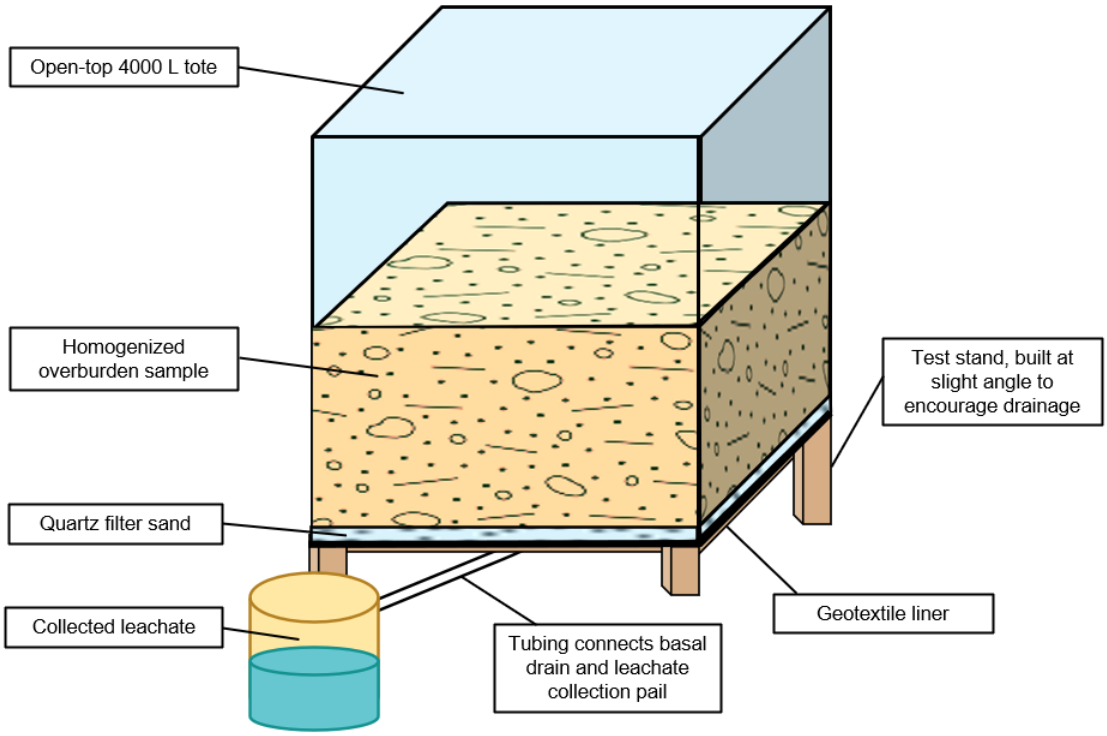

Figure 4.5-2: Conceptual Drawing of an Overburden Field Leach Test

4.6 QUALITY ASSURANCE AND QUALITY CONTROL

4.6.1 LABORATORY CONTINUITY

Several facilities conduct commercial ML / ARD analyses in Canada. Analyses undertaken as part of the baseline geochemical characterization studies were carried out at multiple laboratories, from 2022 to 2025, as detailed in Section 4.2. The use of multiple laboratories is not uncommon for long-term geochemical programs and is acceptable provided that there is continuity in test methods such that the generated data can be considered as one dataset. The following strategies were utilized to maintain continuity among the various laboratory test programs:

- Consistent sample preparation and analytical methods were specified to be used by laboratories so that results were comparable. Methods used were consistent with MEND (2009).
- Where sample mass allowed, replicate samples were completed at the various laboratories to further confirm consistency between methods. If inconsistencies were noted, QA / QC programs we conducted to further evaluate observations and verify test results.
- All detection limits used for the Project underwent an initial review to confirm they were suitable (e.g., below relevant qualitative screening criteria for individual parameters).

For some parameters (including sulphate S and TIC) multiple analytical methods were used dependent upon the analytical facilities at each laboratory. Results were compared to confirm they were consistent across methods.

4.6.2 DETECTION LIMITS

Analytical methods and detection limits used for individual parameters are listed in Table A-1 through Table A-6 of Appendix A. Consistent analytical methods were specified to be used by both laboratories to confirm results were comparable, however minor differences in detection limits may be noted between laboratories. This occurs due to the use of different analytical instruments, calibration, or the use of dilution for specific samples.

As previously described all detection limits used underwent review to confirm they were suitable (e.g., below relevant screening criteria).

Where detection limits varied throughout testing, the range of detection limits used are shown in Tables A-1 through A-6. On isolated occasions, some parameters had a detection limit higher than its respective screening value due to required dilution, as noted in in Tables A-1 through A-6. Detection limit concentrations are also depicted with < in data presented in Appendix B through Appendix N for completeness.

4.6.3 QA / QC PROTOCOLS

All laboratory data received for the Project underwent an initial review to confirm data accuracy and precision. Where available, this included review of laboratory-provided QA / QC protocols such as replicates, duplicates, and certified reference materials as described below:

- Review of blank samples to verify concentrations were generally below detection limits.
- Comparison of duplicate samples results to confirm there was an acceptable relative percent difference between analyses (e.g., generally within 10% for measurements that were at least five times greater than the analytical detection limit).
- Calculation of charge balances for water / leachate samples to confirm they were within the range considered acceptable (e.g., +/- 15%).

- Recalculation of mathematically derived results reported by laboratories (e.g., sulphide S by difference, AP, CarbNP, NPR and CarbNPR).

After the initial review, further QA / QC checks were completed to verify data integrity, including comparison of the following data to identify any inconsistencies between analyses that may signify potential data quality issues:

- Reconciliation of S species, total S content, and S mineralogy.
- Fizz rating information was reviewed and confirmed to not exceed maximum indicated acid strength and volume guidelines for a given sample's NP content per guidance in MEND (2009).
- TC and TIC content.
- NP and CarbNP content, including individual review of negative NP samples where applicable.
- ARD classification based on NPR, CarbNPR and NAG pH criteria was consistent. Where inconsistent, the results could be explained by the sample characteristics and test response.

In addition, drill core samples analyzed at Global ARD, BV, and ACT Labs were run alongside certified reference materials (standards varied by parameter). Analytical results for the certified reference materials showed excellent agreement with standard values and these results are presented in the appended laboratory certificates of analysis (Appendix O).

Furthermore, drill core samples were run in duplicate for key ABA parameters (total S, NP, TIC and TC) as well as for elemental content by both aqua regia digest ICP-MS and four acid digest ICP-MS. Original and duplicate results were compared. Due to the inherent heterogeneity of rock samples, an RPD range of ±25% between the original and the duplicate sample was considered acceptable, and most samples fell within this range. Comparison of duplicate data for drill core is discussed further in Section 5.2. Duplicate testing of drill core samples included:

- Approximately 187 duplicate analyses of total S, and 137 duplicates of sulphate S.
- Approximately 150 duplicate analyses of TIC, NP, and TC.
- Approximately 180 duplicate analyses of for elemental content by both aqua regia ICP-MS and four acid ICP-MS.

In addition to the above approaches, the Project has a large multielement exploration geochemistry database. As such, nearly all drill core samples submitted for ML / ARD analysis had a paired half core analyzed as part of the exploration program (four acid digestion and ICP-MS) (n=3,835). Comparison of the four acid datasets indicated generally good agreement between the analyses.

Select samples were reanalyzed to confirm results and alignment of key parameters if initial data reviews suggested there were potential QA / QC concerns in the original analysis (either systematic or random). Following reanalysis the data were reviewed:

- The original data were retained if the duplicate assessment confirmed the original result.
- In instances where QA / QC concerns were noted in the original data, the reanalysis result was used. Where QA / QC concerns were identified, the reanalysis result appeared to resolve the analytical inconsistencies observed in the original data.

Additional QA / QC programs were conducted for several subsets of drill core and overburden samples. This included verification testing at multiple laboratories where QA / QC concerns were identified. These programs are described in Sections 5.2.4 and 7.2.4.

Specific QA / QC protocols were established where leachates were collected in the field, including for the FLB program. This information is described in detail in Section 5.6.5.

5 PROJECT ROCK

5.1 SUMMARY

Comprehensive geochemical characterization programs were undertaken for representative rock samples from the Project to characterize its metal leaching and acid generation potential. This included a static testing program with 3,885 drill core samples and a kinetic testing program with 84 kinetic tests with dozens of weeks to several years of data. Kinetic testing includes 35 humidity cell tests and 34 column tests operated in the laboratory, and 15 field leach barrel tests operated in the field at the Great Bear Property.

Baseline geochemistry programs for Project rock have been underway for several years. The sampling approach and testing methods utilized are based on the requirements described under the Ontario Mining Act, namely guidance found within the reference document Prediction for Drainage Chemistry for Sulphidic Geologic Materials (MEND 2009), which represents best practice and industry-standard approaches and methodologies for ML / ARD sampling and characterization in Canada.

The scope of the baseline program has progressed over time based on technical findings of the geochemistry programs, plus feedback received from regulatory agencies and stakeholders. Overall, the characterization program for Project rock is highly robust and comprehensive. The magnitude of the collected dataset exceeds standard approaches for similar mining projects completed or undergoing the approvals processes in Ontario.

Static testing results for 3,885 samples indicated that S contents of drill core samples were variable, ranging from below the analytical detection limit (0.01%) up to 10%. Samples of the most abundant rock types (Felsic Volcanic 1, Felsic Volcanic 2) generally had S contents on the order of 0.5 to 0.7%. Samples of ore-grade materials generally had higher S contents (1.3%) compared to mine rock samples (0.39%). However, numerous mine rock samples had S contents that were similar to or higher than the ore-grade samples.

Sulphur was primarily present as the acid-generating sulphide minerals pyrite and pyrrhotite. Sulphate was present in low abundance (median 0.06% sulphate sulphur) in most samples tested by ABA; this result was confirmed by mineralogical testing (R-XRD, and QEMSCAN). Total S was found to be strongly correlated with sulphide content and an accurate measure of the acid generation capacity of the rock (expressed as MPA).

CarbNP was calculated for all samples based on TIC measurements. Overall, the samples exhibited variable CarbNP contents that ranged from 1 to 200 kg $CaCO_3$/t. Most samples had a low neutralization capacity (median CarbNP 11 kg $CaCO_3$/t) although higher CarbNP contents were observed for some specific rock types (e.g., Basalt, CarbNP on the order of 50 kg $CaCO_3$/t). CarbNP was typically similar to or lower than Modified NP, suggesting most neutralization capacity in the samples was present as carbonate minerals, with calcite as the primary carbonate mineral as identified by mineralogical testing.

A CarbNPR (CarbNP/MPA) threshold of 2 was used to classify samples as PAG or NPAG. Approximately 80% of tested drill core samples were classified as PAG by this threshold, including 78% of mine rock samples and 94% of ore-grade samples. Most samples from the LP Central pit (85%) and Viggo pit (67%) were classified as PAG, along with approximately half of the samples (50%) from the underground mine. A majority of mine rock samples from Felsic Volcanic 1 (78%), Felsic Volcanic 2 (90%), Fragmental 1 (75%), Metasediment 2 (98%), and Metasediment 3 (77%) were classified as PAG, whereas most mine rock samples of Fragmental 2 (73%) and Basalt (79%) were NPAG.

Results for the 35 humidity cell tests (63 to 109 weeks of data) supported the classification of samples as PAG or NPAG as determined by ABA testing. Overall, sulphide oxidation rates in the humidity cell tests were low. The data suggest that Project rock may have a range of lag times, including: low sulphide oxidation rates in typical pyrite and pyrrhotite bearing materials leading to long lag times (10 years or longer), low sulphide oxidation rates in high sulphide, low neutralization capacity materials with accessory

sulphides (e.g., sphalerite, galena), and acidification within a limited timeframe in high sulphide, low neutralization capacity samples. Material with a low neutralization capacity and high sulphide content is currently understood to represent a minor component of the overall Project rock.

The observed low sulphide oxidation rates in the samples may be due to trace metal substitution and are currently being assessed in detailed mineralogy programs. Galvanic interactions may also be influencing sulphide oxidation rates, but given the current mineralogical dataset, the prevalence of non-acid generating sulphides is thought to be limited and therefore not notably affecting the observed low sulphide oxidation rates. Kinetic testing continues to be routinely monitored.

Comparison of humidity cell release rates to release rates obtained from 15 field kinetic tests (FLBs) suggests that sulphide oxidation rates under field conditions may be up to 10 times slower than those observed in the laboratory. This is attributed to differences in flushing, temperature, and sample grain size, and indicates that practical lag times in the field could be longer than those currently estimated from humidity cell testing. However, net acid generating conditions may still occur within a limited timeframe for samples with very low neutralization capacity and higher sulphide content, as progression toward acidic conditions was observed for two field tests after one year of monitoring.

Initial static testing including elemental content analysis and short-term leaching tests (SFE tests) identified several parameters of potential interest for neutral metal leaching. Primarily this included As, as solid phase contents were above screening values in 48% of the drill core samples and leachate concentrations were above screening values in 65% of the SFE tests.

The results of kinetic testing demonstrated that As release rates varied distinctly based on the As content of the sample and As sulphide mineralogy present. Different As sulphide associations are also observed among the different Project rock types, indicating that different As leaching behaviours are present amongst the various rock types. Comparisons of laboratory and field kinetic test data generally showed alignment, whereby samples with a higher solid phase As content generally had higher As release rates than samples with a lower solid phase As content. However, As release rates were lower for some materials with a lower As solid phase content in field kinetic tests relative to laboratory tests, possibly due to reduced reactivity under field conditions.

For major rock types including Felsic Volcanic 1 and Felsic Volcanic 2, if As was present in the samples it typically occurred in pyrite (As-bearing pyrite) or as arsenopyrite (which was typically present with pyrite or pyrite and pyrrhotite). These samples were observed to leach As at relatively low rates (e.g., below the interim PWQO screening value) except where solid phase As concentrations were elevated (>100 mg/kg). These elevated As content samples represent a small fraction of the dataset overall and much of the Felsic Volcanic 1 and Felsic Volcanic 2 rock was determined to be non-As leaching.

Other rock types including Metasediment 2, Metasediment 3, Fragmental 1, Fragmental 2, and Basalt hosted As in As-bearing pyrite, arsenopyrite, and the As sulphide mineral gersdorffite-cobaltite. This mineral is understood to occur in isolated samples and not be present in the bulk of the Project rock. However, when these samples had a higher proportion of gersdorffite-cobaltite and little pyrite / pyrrhotite, they had a higher potential for As leaching as a result of the lack of secondary Fe-oxyhydroxide surfaces (produced from pyrite / pyrrhotite oxidation) to adsorb the As released during gersdorffite-cobaltite oxidation. This behaviour was observed for samples of Metasediment 2, Metasediment 3, Fragmental 1, Fragmental 2 where solid phase As was >12 mg/kg and for some Basalt samples where solid phase As was >46 mg/kg. Below these solid phase content thresholds, As leaching rates from these rock types are expected to be low.

Other elements that were above screening values in terms of their solid phase contents or leachate concentrations in short-term leaching tests did not appear to be of interest for metal leaching under neutral pH conditions for the bulk of the Project rock based on low release rates in the extensive laboratory and field kinetic testing programs undertaken.

Project rock generally contained low levels of Hg with no potential for Hg leaching observed in kinetic tests. Greater than 99% of the samples had solid phase Hg concentrations that were below screening values and 90% of the overall dataset had Hg concentrations that were at or below the analytical detection limit (0.005 to 0.05 mg/kg). Mercury release rates in all kinetic tests were based on

concentrations at or near the analytical detection limit (0.000005 to 0.00001 mg/L) for all tests for the duration of testing. Ultra-trace Hg analysis (detection limit of 0.00000004 mg/L) was recently initiated for ongoing kinetic tests to supplement the currently available data. Results of this analysis confirms very low Hg release rates in humidity cell tests (less or equal to 0.0000002 mg/m^2/week).

NAG leachate analysis indicated that several metals (Ag, Al, As, B, Cd, Co, Cr, Cu, Fe, Mo, Ni, P, Pb, Se, Tl, U, V, W, and Zn) may be of potential interest under acidic leaching conditions. Humidity cell tests generally showed longer lag times to net acidic conditions and stable acidic leaching conditions have not yet developed for many PAG samples undergoing kinetic testing. Metal release rates for the kinetic tests will continue to be monitored.

5.2 STATIC TESTING

5.2.1 OVERVIEW

A static testing program was undertaken to assess the metal leaching and acid rock drainage (ML / ARD) potential of rock expected to be encountered during mining. The static testing program included a total of 3,885 samples of archived drill core from 342 drillholes within the proposed mine volume. Samples represented rock from the LP Central pit, Viggo pit, and underground mine, based on current mine design information. Samples were selected to represent both mine rock and ore-grade materials for all key Project lithologies, including Felsic Volcanic 1, Felsic Volcanic 2, Metasediment 2, Metasediment 3, Fragmental 1, Fragmental 2, and Basalt.

The 3,885 sample dataset comprised samples collected as part of several programs:

- 933 samples were collected as part of initial baseline programs for the Project between 2022 and 2024. These samples were analyzed by full ABA analysis and elemental content analysis, as well as more detailed static testing methods including NAG pH, SFE, NAG leachate, and R-XRD.
- 2,952 samples were collected as part of a supplemental baseline program for the Project in 2024. Samples in this dataset were analyzed by partial ABA testing (total S, TIC, and TC), as well as elemental content analysis.

The sampling approach and testing methods utilized for the drill core static testing program are based on the requirements described under the Ontario *Mining Act*, namely guidance found within the reference document *Prediction for Drainage Chemistry for Sulphidic Geologic Materials* (MEND 2009), which represents best practice and industry-standard approaches and methodologies for ML / ARD sampling and characterization in Canada.

The static testing program for Project rock from drill core samples was comprehensive and robust. The scope of the program and the magnitude of the collected dataset exceeds standard approaches for similar mining projects undergoing the approvals process in Ontario.

5.2.2 DRILL CORE SAMPLES

Samples were selected through review of drill core logs, exploration geochemistry data consisting of continuous (1 m interval) multielement ICP assay results, and geologic information including geologic models. Currently available data for the overall Great Bear Project mine volume includes exploration assay data for over 500,000 samples analyzed by four acid ICP-MS. A total of 3,885 geochemical characterization samples have been collected to date representing the overall Great Bear Project rock mass.

The spatial location of the drill core samples relative to the currently planned mine volume is shown in Figure 5.2-1. Cross sections are provided in Appendix B.

The drill core samples comprised:

- 3,432 samples representative of the open pit volume, including LP Central pit and Viggo pit.
- 453 samples representative of the underground mine volume.

The majority of samples were located within the proposed mine volumes, with some samples located within a 50 m buffer zone around the proposed open pits. A wider buffer (up to 200 m away for some samples but typically within 50 to 75 m) was used for the underground samples due to core availability in some areas of the deeper underground mine. Deeper levels of the underground mine will be developed later in the Project and sample coverage in these areas will be supplemented as additional drilling is conducted. Based on currently available geological and block model data, it is assumed that the composition of rock from these deeper levels will be geochemically similar to the rock that has been sampled to date.

Major and minor rock types expected to be encountered during the currently planned mine development were targeted as part of drill core sampling and analysis. Key rock types for the LP Central pit, Viggo pit, and underground mine are shown in Table 5.2-1. The LP Central pit is the volumetrically largest of the mine developments.

For the purposes of this assessment, rock at the Project has been classified into two groups:

- Ore-grade materials: samples with an economic gold content.
- Mine rock: all rock from the mine volume excluding ore-grade materials and including future exposed rock surfaces.

Ore-grade materials are most often associated with the Felsic Volcanic 1 and Felsic Volcanic 2 rock types. However, these lithologies also comprise a notable proportion of the mine rock.

Samples were selected through review of drill core logs, exploration geochemistry data consisting of continuous (1 m interval) multielement ICP assay results, and geologic information including geologic models and cross sections of the open pits and underground mine.

Drill core recovered from within the last 10 years was targeted for sample collection. Although more recent drill core was the primary focus of sampling, a subset of samples (n=49) from older holes (drilled between 2002 and 2007) were included. These samples were included to permit more complete spatial coverage and for comparative purposes to assess mine rock reactivity (i.e., weathering effects from 15 to 20 years of exposure).

Individual samples generally comprised 1 to 1.5 m intervals of drill core, spaced at 5 to 50 m intervals from most drill holes. Samples covered a range of rock characteristics, including rock types, alteration types, and sulphide mineral contents. Samples were collected at a higher or lower frequency from some drill holes so that sufficient coverage of key rock types for ML / ARD testing could be achieved.

A summary of the drill core samples is presented in Table 5.2-2. The distribution of the samples among the various rock types generally aligned well with the overall rock type proportions in the mine volume. Samples were collected by Great Bear Resources based on sample lists from WSP. Samples were collected in three campaigns, in December 2022, May 2023, and June 2024.

5.2.3 ANALYTICAL TEST METHODS AND SCREENING APPROACH

Drill core samples were tested by a suite of static testing methods as described in Section 4, including ABA, NAG pH, elemental content by aqua regia ICP-MS and four acid ICP-MS, SFE, NAG leachate, and R-XRD. A summary of the tests completed is provided in Table 5.2-3. Detailed information on these methods and sample preparation information is presented in Appendix A.

Laboratory analyses were carried out at commercial ML / ARD laboratories from 2022 to 2024, as listed below:

- Static testing of 933 drill core samples, including ABA, NAG pH, elemental content by aqua regia ICP-MS and four acid ICP-MS, SFE, NAG Leachate, and R-XRD, were conducted at the following laboratories:
  - Global ARD in Burnaby, British Columbia.
  - SGS in Lakefield, Ontario.
- Additional static testing of 2,952 drill core samples for TIC, TC, total S, and elemental content by aqua regia ICP-MS and four acid ICP-MS, was conducted at:
  - BV in Vancouver, British Columbia.
  - ACT Labs in Ancaster, Ontario.

An overview of the static test methods used for the ML / ARD assessment is discussed below.

- ABA testing was conducted to evaluate the balance of potentially acid generating and neutralizing minerals in the samples.
  - As shown in Table 5.2-3, 933 samples underwent full ABA analysis, which included determination of paste pH, total S by Leco furnace, sulphate S by HCl leach, sulphide S by difference (total S less sulphate S), TC by Leco furnace, TIC by HCl leach and Leco furnace, and Modified NP[2].
  - Partial ABA analysis was conducted on samples from the open pit to supplement the full ABA analyses, including 2,952 samples analyzed for S by ICP-MS and TIC by HCl leach / Leco, 433 samples analyzed for of total S, TC, and Modified NP[1], and 15 samples analyzed for total S and TC.
  - For both full and partial ABA analyses, TIC was used to calculate the CarbNP. Total S by Leco was used to calculate the MPA where full ABA test results were available. As discussed in Section 5.2.5 Leco S showed good alignment with aqua regia ICP-MS S. Therefore, where Leco S was not analyzed, ICP S was used to calculate MPA.
  - As described in Section 5.2.5, neutralization capacity was primarily derived from carbonate minerals, however some samples with lower CarbNP values contained low amounts to no carbonate minerals. Net neutralizing carbonate (i.e., calcite) was identified as the main source of neutralization capacity in samples tested by R-XRD and detailed mineralogy (Section 5.3). Therefore, for assessment purposes, NPR values were calculated using CarbNPR (CarbNP/MPA), which assumes that only carbonate minerals are available for neutralization, and all S minerals generate acidity. Sample classification as PAG or NPAG was determined based on the criteria provided in Table 3.3-1.
  - Project information and data indicated that several sulphide minerals including pyrite (FeS_2), pyrrhotite (Fe_7S_8), sphalerite (ZnS), and galena (PbS) are observed to be present in the rock (see Section 5.2.6). Geological observations indicated that other sulphides, arsenopyrite (FeAsS) and chalcopyrite ($CuFeS_2$), may also be present, but they appear to be isolated or present in low abundances based on the baseline data collected. The oxidation of pyrite, pyrrhotite, and chalcopyrite generates acidity, whereas the oxidation of monosulphide minerals such as sphalerite and galena does not. Therefore, elemental content data were used to estimate the quantity of S associated with non-acid generating sulphides (ZnS and PbS) in all samples and evaluate the need to consider the potential presence of these phases when calculating acid generation capacity for the samples. The estimated proportion of acid generating, and non-acid generating sulphide phases (inferred from elemental content results) is discussed further in subsequent sections.

[2] Modified Sobek NP based on MEND (1991) which is an update to the 1989 Lawrence Modified NP method.

- NAG testing was conducted to complement the ABA analyses. NAG results were screened against NAG pH criteria for PAG and NPAG materials (AMIRA 2002) and assessed in conjunction with NPR values from ABA testing.
- Solid phase elemental content analysis was conducted by aqua regia digestion and ICP-MS scan for environmental screening purposes, including measurement of Hg, Ag, Al, As, Ba, B, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, P, Pb, Sb, Se, Si, Sn, Sr, Ti, Tl, U, V, W, and Zn. Solid phase elemental content results were compared to 10 times the crustal abundance values presented in Price (1997) for screening purposes. Sample concentrations greater than the screening value were considered enriched in those elements. This approach is used to screen the samples for elemental enrichment based on standard screening values and does not provide a direct assessment of metal leach potential or resulting water quality. Elements that were enriched in the solid phase were given additional consideration in subsequent metal leaching assessments (SFE, NAG, and kinetic testing).
- Elemental content analysis was also determined for all samples by four acid digest and ICP-MS scan, including measurement of Ag, Al, As, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, P, Pb, Sb, Se, Si, Sn, Sr, Ti, Tl, U, V, W, and Zn. This was conducted to support use of the data in conjunction with the exploration ICP data set (which uses the four acid digestion method).
- Short-term leaching tests were conducted on the samples. This included:
  - SFE testing was conducted to assess the potential release of soluble metals during the initial (i.e., short-term) stages of weathering. Leachates were analyzed for pH, EC, alkalinity, acidity, sulphate, and metals (Hg, Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, W, and Zn).
  - NAG leachate testing was conducted to identify parameters of potential interest under net-acidic leaching conditions. Sequential NAG tests (the same sample subjected to two or more NAG tests in succession) were conducted as part of NAG leachate testing for samples with >1% S (AMIRA 2002). Leachates were analyzed for pH, EC, alkalinity, acidity, sulphate, and metals (Hg, Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, W, and Zn).
  - The results of short-term leaching tests, including SFE and NAG leachate test results, were compared to Ontario PWQO for protection of aquatic life, including both interim PWQO and PWQO values, for screening purposes. The short-term leaching tests and screening approach are not a direct assessment of mine water quality and comparisons to screening values hold no regulatory significance. Elements that were above screening values were further assessed using kinetic tests.
- Mineralogical testing was conducted by R-XRD to identify major and minor minerals, including those potentially involved in acid-generating and neutralizing reactions.

5.2.4 QUALITY ASSURANCE AND QUALITY CONTROL

Data was reviewed for QA / QC on an ongoing basis during data collection. QA / QC samples for solid phase analysis (i.e., ABA and elemental content) included:

- Pulp duplicates: two analyses performed on splits of the same pulverized material.
- Prep duplicates: two analyses performed on splits from the same parent sample that were pulverized separately.

Pulp duplicate analyses included samples initially run at SGS Lakefield and re-analyzed at Global ARD as well as samples initially run at Global ARD that were analyzed in duplicate as part of routine QA / QC practices. QA / QC analysis included measurement of total S (Leco furnace), Modified NP, TIC (HCl leach / Leco furnace), TC (Leco furnace), and solid phase elemental content (aqua regia ICP-MS and four acid ICP-MS).

A subset of samples initially analyzed at SGS Lakefield were randomly re-selected for QA / QC analysis at Global ARD. In addition, select samples were reanalyzed to confirm results and alignment of key

parameters if initial data reviews suggested there were potential QA / QC concerns in the original analysis (either systematic or random). Following reanalysis, the data were reviewed:

- The original data were retained if the duplicate assessment confirmed the original result.
- In instances where QA / QC concerns were noted in the original data, the reanalysis result was used. Where QA / QC concerns were identified, the reanalysis result appeared to resolve the analytical inconsistencies observed in the original data.

Duplicate tests are summarized in Table 5.2-4 and full results of duplicate testing are provided in Appendix B.

RPDs were calculated for duplicate sample runs for key ABA parameters, as well as elemental content analysis (both aqua regia digest and four acid digest ICP-MS). Due to the inherent natural heterogeneity of rock samples, an RPD range of ±25% was considered acceptable.

- Most samples fell within this range and typically had RPDs of ±10 to 15% or less.
- RPDs that were outside of this range generally occurred for samples with very low concentrations (typically below or near the analytical detection limit), and comparison of the measured values indicated good agreement despite their slightly elevated RPD. This was noted most often in solid phase elemental content results for Sb, Se, Sn, Hg, Ag, B, and Bi, which had different analytical detection limits at SGS Lakefield and Global ARD.
- Larger RPD values were sometimes observed for elements: associated with refractory minerals (i.e., those that are difficult to dissolve in solution), prone to volatilization during digestion (i.e., loss from solution due to evaporation), sensitive to solution stability, or requiring stronger oxidizers (including Cr, Zr, As, Mo, and V).

In addition to duplicate sample analyses, results of four acid testing (n=3,882 samples) were compared to their matching (other drill core half) analysis in the Project exploration geochemistry dataset. This comparison included S, As, Cd, Co, Cr, Cu, Fe, Mo, Ni, Pb, Sb, Tl, U, V, W, Y, Zn and Zr. Excellent agreement between the measurements was observed for Co, Cu, Fe, Ni, S, V, Y, Zn and Zr, with between 70% and 90% of samples agreeing within ±10% and 90% to 99% of samples agreeing within ±25%. A majority of As (67%), Cr (69%) and Pb (80%) measurements agreed within ±25%. Other parameters (Cd, Mo, Sb, Tl, U, and W) frequently had higher RPD values, primarily due to differences in analytical detection limits used. RPD values >25% sometimes occurred for detectable values and was attributed to heterogeneity between the half core samples.

Samples analyzed at Global ARD were additionally run alongside certified reference material (standards varied by parameter). Analytical results for the reference material showed excellent agreement with standard values and these results are presented in the attached laboratory certificates of analysis (Appendix O).

QA / QC of leachate samples from SFE and NAG testing was also completed via charge balancing. The analyzed solutions were typically balanced within 10%, which is well within the accepted range.

- It was noted that during QA / QC review for the overburden samples (Section 7.2.4), leachate concentrations of Fe and some trace metals were elevated in SFE leachates from SGS Lakefield compared to those from Global ARD. Routine QA / QC checks (charge balancing, method blanks, and laboratory duplicates) on the data did not identify any issues, and the samples were analyzed across several batches and dates. Duplicate SFE analysis of five drill core samples was conducted at both SGS Lakefield and Global ARD and confirmed this trend (Appendix B).
- Subsequent discussions with SGS Lakefield could not clearly confirm detailed method information. It was unclear if the samples had undergone end over end shaking or if sufficient settling of particles was allowed after shaking and prior to leachate filtration. Global ARD utilized a gyratory shaker as recommended in MEND (2009). Elevated SFE leachate concentrations at SGS Lakefield are thought to be a product of the method used resulting in additional fine material present in the solution (see Appendix A for additional details).

- Despite the observed concentration differences between the two labs, the SGS Lakefield SFE leachate dataset was retained for assessment purposes and considered adequate for initial data screening. The data are considered conservative given the observed trends and a robust kinetic testing program (including field and lab tests, see Sections 5.4, 5.5, and 5.6) has been undertaken to verify metal leaching potential.

5.2.5 RESULTS

Key static testing results are summarized below. Selected figures are attached. All results and statistical summaries of results are provided in Appendix B.

Acid Generation Potential

Total S results measured by Leco furnace were available for 1,366 samples. Among this dataset, S contents were variable, with concentrations ranging from approximately 0.01% (the analytical detection limit) to 10%, with a median S content of 0.43% (Figure 5.2-2 and Figure 5.2-3; Table 5.2-5; Tables B1 and B2 of Appendix B).

- Samples from LP Central pit had higher median S content (0.73%) than samples from the Viggo pit (0.26%) or underground mine volume (0.25%); however, the range of S contents for samples from the open pits and the underground were similar, approximately 0.01% to 10%.
- Both mine rock and ore-grade samples were available for the open pits and the underground. Higher median S contents were observed in samples of ore-grade materials (1.3%) compared to mine rock (0.39%). However, numerous mine rock samples had S contents that were similar to, or even higher than, the ore-grade samples.
- Among the mine rock samples, median S contents of Felsic Volcanic 1 (0.52%) and Felsic Volcanic 2 (0.76%) were the highest among all key lithologies. Sulphur contents for other rock types were generally lower including Fragmental 1 (median of 0.33%), Metasediment 2 (median of 0.37%), Metasediment 3 (median of 0.16%), Basalt (median of 0.20%), and Fragmental 2 mine rock (median of 0.06%) were much lower than other lithologies. Most key rock types showed similar ranges of S contents including Felsic Volcanic 1, Felsic Volcanic 2, Metasediment 2, Metasediment 3, Fragmental 1, and Fragmental 2.

Nine hundred and thirty-three samples were analyzed for total S by Leco furnace and sulphate S by HCl leach. Sulphide S by difference was determined for these samples. The relationship between total S and sulphide S content is presented in Figure 5.2-2 and Figure 5.2-3 and indicated that S was primarily present as sulphide S in samples. This observation is supported by the findings of R-XRD and detailed mineralogy (Section 5.3), which indicated that S was primarily present as the sulphide minerals pyrite and pyrrhotite, with minor to trace amounts of other sulphides, including sphalerite and galena in isolated samples.

- Sulphate S concentrations were low, with a median sulphate S concentration of 0.06%. Median sulphate concentrations were similar between the LP Central pit (0.05%), Viggo pit (0.05%), and underground (0.07%). In general, samples with higher total S content also had higher sulphate S content. However, some samples with higher total S content had a low (i.e., below detection) sulphate content. This was most common in samples from the LP Central pit, however there was not a clear association of samples with low sulphate S and high total S with other sample properties including lithology, core age, sample location, or sample depth.
- A higher sulphate S content (>1% and up to 8.5%) was observed for 28 of 933 samples (3% of samples). Based on sample mineralogical information (pyrrhotite is commonly identified) the higher sulphate S content of these samples was attributed to the dissolution of pyrrhotite during the HCl leach test. To date, Project geology, mineralogical testing, and ABA testing suggest that most S is expected to be present as sulphide and the detected sulphate concentrations in these samples are considered an artefact of the HCl leach test procedure and the specific sample mineralogy (pyrrhotite). As shown in Figure 5.2-2 and Figure 5.2-3, many samples with higher proportions of

sulphate S (i.e., those sitting below the 1:1 line shown) that were tested by R-XRD contained pyrrhotite. It is noted that not all samples shown in Figure 5.2-2 were tested by R-XRD.

- Additional supplemental S speciation testing (sodium carbonate [Na_2CO_3] leach and nitric acid [HNO_3] leach) on a subset of samples (n=50) confirmed that sulphides represent the main S species in the samples (Table B-3 of Appendix B).
  - Sulphate S contents analyzed by Na_2CO_3 leach indicated low levels of sulphate. Sulphate S ranged from 0.01% (the analytical detection limit) to 0.04%. Of the 50 samples, 39 had sulphate S concentrations by Na_2CO_3 leach that were below the analytical detection limit (0.01%).
  - The results of the Na_2CO_3 leach test agreed with the results of the HCl leach test for 44 out of 50 samples. These samples had low sulphate S contents, consistent with the results of detailed mineralogical testing (Section 5.3) which indicated that sulphate (as gypsum / anhydrite) was present in low abundance (0.001% to 0.028%) in all samples. Other sulphate phases were not detected during detailed mineralogical testing. One of the 198 samples tested by R-XRD contained 0.6% jarosite; however, this measurement could not be confirmed through other testing approaches.
  - For six samples, differences between the HCl and Na_2CO_3 leach results were observed whereby HCl leach results showed higher concentrations of sulphate S; R-XRD results were available for five of these samples, and four contained notable (3 to 25 wt.%) pyrrhotite, indicating that some pyrrhotite may have dissolved during the HCl leach test and resulted in the higher sulphate S concentration by that method.
  - Results of the HNO_3 leach test showed that for most samples, the sulphide content of the sample was underestimated by this test. Underestimation of sulphide by the HNO_3 leach test is common for samples that contain high amounts of crystalline pyrite (MEND 2009).

Project geologic information and mineralogical test results indicated that some non-acid generating sulphide minerals, such as sphalerite (ZnS) and galena (PbS) may be present in the samples alongside acid generating Fe sulphide minerals (pyrite and pyrrhotite). To confirm that non-acid generating sulphide contents were low amongst the entire dataset, elemental content data for the drill core samples (Tables B-3 of Appendix B) was used to estimate the quantity of these phases present in the samples. The results of this evaluation suggested that for approximately 99% of samples (n=1,361), most of the S in the samples (i.e., typically >98%) is likely associated with acid generating phases, (i.e., pyrite and / or pyrrhotite). Results of mineralogical testing (Section 5.3) were consistent with this observation. Therefore, no adjustment was made to AP and MPA calculations to account for low levels of non-acid generating sulphides.

Sulphur concentrations measured by Leco furnace and aqua regia digest ICP-MS were compared for 1,366 samples to assess whether ICP S measurements could be used to calculate an analogue total S content for samples that did not undergo total S analysis by Leco furnace in order to have greater coverage of material from the LP Central pit, which represents the bulk of the mine volume. As shown in Figure 5.2-4 and Figure 5.2-5 S measured by Leco and S measured by aqua regia digest and ICP-MS were highly consistent. A relationship of approximately 1:1 was observed for most samples. The relative percent difference between the two values for most samples was within ±10%. For completeness, a comparison of total S measurements by Leco furnace and four acid ICP-MS was also considered. Results of this comparison also showed that most samples had four acid S values that were within a ±10% relative difference between the total S value measured by Leco furnace.

Sulphur content by ICP (aqua regia) was available for 2,519 samples that were not analyzed for total S by Leco furnace. The range of S contents and median S contents of this dataset were consistent with the Leco S dataset. As most S has been established to be sulphide S and Leco S and ICP S were highly consistent, the ICP S data was used as a proxy for total S where it was not directly analyzed. Therefore, for assessment purposes MPA values were calculated based on Leco S and aqua regia ICP S where Leco S data was not available.

CarbNP data was calculated for 3,885 samples based on TIC measurements. Overall, the samples exhibited variable CarbNP contents (Table 5.2-6, Tables B-1 and B-2 of Appendix B). The median CarbNP of all samples was 11 kg $CaCO_3$/t with most samples ranging from approximately 1 to 200 kg $CaCO_3$/t (Table 5.2-6). Six samples had a notably higher CarbNP content relative to the rest of the dataset, with CarbNP values on the order of 340 to 450 kg/$CaCO_3$/t. The high CarbNP of these samples was attributed to the presence of large calcite veins; such materials are understood to be generally isolated and limited in abundance within the mine volume.

- Median CarbNP contents were relatively similar between the LP Central pit (11 kg $CaCO_3$/t) and Viggo pit (6.7 kg $CaCO_3$/t), and slightly higher for samples from the underground mine (18 kg $CaCO_3$/t). Median CarbNP values for mine rock (11 kg $CaCO_3$/t) and ore-grade samples (12 kg $CaCO_3$/t) were similar.
- A comparison of key Project lithologies (including Felsic Volcanic 1, Felsic Volcanic 2, Metasediment 2, Metasediment 3, Fragmental 1, and Fragmental 2) indicated similar CarbNP content distribution from samples among most lithologies. Felsic Volcanic 1 and Felsic Volcanic 2, which represent the most abundant mine rock types, had median CarbNP contents of 12 and 13 kg CaCO3/t, respectively. Basalt had a notably elevated median CarbNP (49 kg $CaCO_3$/t) relative to other major lithologies, while Metasediment 2 (1.8 kg $CaCO_3$/t) and Metasediment 3 (3.9 kg $CaCO_3$/t) had notably lower median CarbNP contents.

Both Modified NP and CarbNP measurements were available for 1,368 samples. The relationship between Modified NP and CarbNP is presented in Figure 5.2-6 and Figure 5.2-7 and indicated the following:

- CarbNP was typically similar to or slightly lower than Modified NP for most samples with a Modified NP >20 kg $CaCO_3$/t, indicating that most of the neutralization capacity was present as carbonate minerals in these samples. This was consistent with the results R-XRD which indicated that most (>90%) of the samples tested contained calcite as the primary source of NP.
- Samples with a lower Modified NP content (i.e., <20 kg CaCO3/t, n=763 samples) generally had low levels of CarbNP (i.e., generally 5 kg CaCO3/t) suggesting that neutralization capacity was primarily derived from non-carbonate minerals in these samples. Of the samples in this group, 180 (24%) had no detectable CarbNP. The samples with low to no detectable CarbNP were primarily samples of Felsic Volcanic 1, Felsic Volcanic 2, Fragmental 1, Fragmental 2, Metasediment 2, or Metasediment 3 samples. Two samples (one Metasediment 2 and Felsic Volcanic 1) had marginally negative Modified NP values (e.g., -0.5 kg $CaCO_3$/t), which can be due to the potential presence of low levels of stored acidity or due to analytical precision [3]. Additionally, these samples represent a fractional percentage of the dataset (approximately 0.05%), and negative NP values or evidence of stored acidity has not been observed in other samples.
- Forty-seven samples (e.g., 3% of the dataset), including samples of Felsic Volcanic 1, Felsic Volcanic 2, Basalt, Fragmental 1, Metasediment 2, Metasediment 3, and Argillite had CarbNP values that were slightly greater than their respective Modified NP values, suggesting that some of the neutralization capacity in these isolated samples was present as non-net neutralizing carbonate minerals (e.g., Fe carbonates potentially including siderite, ankerite, and ferroan dolomite). R-XRD confirmed this information; where non-net neutralizing carbonates were identified, they were typically present at low abundances (<1 wt.%) and often co-occurred with calcite and dolomite. In most samples, non-net neutralizing carbonates represented a small fraction of the overall carbonate minerals present.

Paste pH values were available for 933 samples. Paste pH was circumneutral to alkaline ranging from approximately 6.5 to 10 (Tables B-1 and B-2 of Appendix B).

[3] These samples were collected as part of the supplemental baseline program for the Project in 2024 and are part of the partial ABA dataset. No corresponding measurements of paste pH or sulphate are available.

Ninety-nine percent of the samples (n=3,836 of 3,885 samples) collected for static testing were obtained from drilling programs conducted over the last six years. In some cases, samples were collected from older drillholes (advanced between 2002 and 2007) to provide greater coverage of the underground mine. This included the drillholes DL-2005-14 (n=5 samples), DC-13-07 (n=5 samples), BR-211 (n=36 samples), DL-04-10 (n=1 sample), DL-04-11 (n=1 sample), DL-04-12 (n=1 sample). To assess potential effects from weathering in storage on these samples, available sulphate S and CarbNP contents were compared among the dataset on the basis of sample age at the time of testing. Higher sulphate S and / or lower neutralization capacity contents can suggest that archived drill core may have weathered in storage, which can influence interpretation of ABA test results as well as provide insight into the reactivity of the drill core.

- Comparison of ABA test results among drill core samples obtained from drilling over the last five years showed no patterns in S content or speciation and CarbNP or Modified NP content related to core age. Available sulphate S measurements of the older samples (n=13 measurements) indicated that sulphate contents were generally low and near the analytical detection limit (0.01%) for most samples. CarbNP was calculated for all samples and a range of CarbNP contents from approximately 0.7 to 124 kg $CaCO_3$/t was observed, similar to what was seen for more recent drill core samples. This suggests that older drill core samples (15 to 20 years old at the time of testing) have undergone minimal changes over time.

Acid generation potential was evaluated based on CarbNPR (CarbNP/MPA) values (Table 5.2-7; Tables B-1 and B-2 of Appendix B). As some samples contained low levels of CarbNP and notable sulphate S contents (largely due to artefacts related to pyrrhotite dissolution in the HCl leach test, see Section 4), CarbNPR was considered a more appropriate approach to classify the acid generation potential than NPR (NP/AP).

Results based on CarbNPR are presented below. CarbNPR could be calculated for 3,885 samples based on the available data. This included CarbNP directly analyzed by TIC and MPA based on Leco S and ICP S.

- Overall, 80% of drill core samples were classified as PAG, including 78% of mine rock samples and 94% of ore-grade samples (Table 5.2-7; Figure 5.2-8 and Figure 5.2-9).
- When mine area is considered, approximately half of the samples from the underground mine were NPAG. Most of the samples from LP Central pit (85%) and Viggo pit (67%) were PAG.
- When rock type is considered, a majority of Basalt (79%) and Fragmental 2 (73%) mine rock samples were classified as NPAG. A majority of Felsic Volcanic 1 (78%), Felsic Volcanic 2 (90%), Fragmental 1 (75%), Metasediment 2 (98%), Metasediment 3 (77%), and Argillite (92%) mine rock samples were classified as PAG.
- Among samples identified as PAG by CarbNPR, 2,539 samples (82% of PAG samples) had CarbNP contents ≤20 kg $CaCO_3$/t. This primarily included samples of Felsic Volcanic 1 (58%), Felsic Volcanic 2 (16%), and Metasediment 2 (15%), though other rock types including Metasediment 3, Fragmental 1, Fragmental 2, Argillite, Basalt, and other lithologies were present among this group. Ninety percent of these samples were from the LP Central pit, seven percent were from the underground mine volume, and three percent were from the Viggo pit.
- Approximately 21% of the samples (n=197) had CarbNPR values between 1 and 2, indicating that these samples have an uncertain acid generating potential.

NPR (NP/AP) was also evaluated, for completeness (Figure 5.2-10 and Figure 5.2-11). NPR values were calculated for 933 samples.

- Differences in sample classification by NPR compared to CarbNPR was primarily noted for a subset of samples (n=155 of samples) with relatively low total S content (average 0.25%), low CarbNP content (<20 kg $CaCO_3$/t, including 29 samples with below detection TIC concentrations) but higher NP content. These samples were classified as PAG by CarbNPR but NPAG by NPR. Non-carbonate minerals represent the primary source of neutralization capacity in these samples.

- Given the low S content of the samples, non-carbonate minerals may provide a suitable source of buffering depending on neutralization capacity and acidity release rates. Ongoing kinetic testing will be used to assess the behaviour of such samples. For current Project purposes, as these samples have a CarbNPR ≤2 they are classified as PAG.

NAG pH analyses were available for 658 samples. The results of NAG testing generally agreed with the results of ABA testing, including agreement between both tests observed for approximately 70% of the samples (Figure 5.2-12 and Figure 5.2-13; Table B-4 of Appendix B).

- Approximately 28% of the tested samples (n=182 samples) had a NAG pH ≤4.5 and were classified as PAG. This was consistent with the classification of these samples based on ABA testing (CarbNPR ≤2).
- Most (i.e., 72% of samples, n=476) of the samples had a NAG pH >4.5 and were classified as NPAG by NAG testing.
  - Approximately 57% of these samples (n=272) were classified as NPAG by ABA testing (CarbNPR >2) and have a low probability of producing net acidity in the future.
  - Approximately 43% of these samples (n=204) classified as NPAG by NAG testing were classified as PAG by ABA testing (CarbNPR ≤2).
    - For 51 of the 204 samples, the apparent low reactivity during the NAG test was attributed to contents of S ≥1% and the resulting incomplete oxidation of sulphides during the test.
    - A total of 106 of the 204 samples with <1% S were classified as PAG based on CarbNPR and NPAG based on NPR. These samples often had much lower CarbNP than Modified NP. The NAG pH results for these samples suggests that samples may have neutralization capacity derived from non-carbonate minerals. For these samples CarbNPR may overestimate their acid generation potential as the neutralization capacity is primarily derived from reactive non-carbonate neutralizing minerals.
    - Forty-seven of the 204 samples with inconsistent results by both methods had lower levels of S (approximately 0.2 to 0.9%), inferred to be present as sulphide S based on ABA test results. All but one of these samples was classified as uncertain by their NPR value (NPR 1-2). Inconsistent results for these samples may be attributed to subsample variability or the presence of slow-reacting sulphide phases (i.e., those that produce little acidity) in the NAG test. Pyrrhotite, which may be present at low levels based on mineralogical testing, may also undergo incomplete oxidation during the NAG test, and underestimate acid generation potential.

Overall, the NAG pH results are generally supportive of the use of a CarbNPR threshold of 2 for separating NPAG and PAG rock (Figure 5.2-12). All samples with CarbNPR >2 had NAG pH >4.5. However, a notable proportion of samples with a CarbNPR ≤2 had NAG pH >4.5. The NAG pH response in some samples could be explained by potential partial oxidation of sulphides in some of the samples (e.g., TS >1%), however, numerous samples had a lower S content, CarbNPR between 1-2, and NAG pH values >4.5.

Given the influence of S content on acid generation potential, NAG pH results were compared to the total S data for the samples. This comparison showed the following:

- All samples with total S measurements (Leco furnace) ≤0.15% that were subject to NAG pH testing (n=197) were classified as NPAG by the NAG test regardless of their CarbNPR value (i.e., all samples with CarbNPR ≤2 and TS <0.15% were NPAG by the NAG test).
- Nearly all (99%) of these samples contained more non-carbonate NP than CarbNP and the results suggested that neutralization capacity contributions from non-carbonate minerals may be able to buffer the acidity generated during sulphide oxidation in these samples.

Overall, the results indicate that a total S threshold can be used to supplement the classification of acid generation potential of the samples based on CarbNPR. Using this, samples with a total S ≤0.15% are classified as NPAG regardless of CarbNP content, and samples with >0.15% total S will continue to be classified based on their CarbNPR value. Kinetic test results to date are supportive of a 0.15% sulphur threshold (Sections 5.4 to 5.6).

Elemental Content

Results from elemental content analysis of 3,885 samples are discussed below. All results and statistical summaries are provided in Appendix B, Tables B-4 to B-9.

The proportions of samples greater than 10 times crustal abundance screening values are summarized in Table 5.2-8 for selected elements. The following observations were made with respect to elemental enrichment in the samples for key metals:

- Solid phase As concentrations were greater than the screening value (18 mg/kg) in 48% of samples (n=1,885 samples). Arsenic concentrations were low overall (median 17 mg/kg). Most samples (approximately 80%) contained 0.1 to 60 mg/kg As. A small subset of samples had higher As concentrations, with isolated samples (n=3) containing >1% As.
  - Approximately 45% of the mine rock samples (n=1,572 samples) and 80% of the ore-grade samples (n=311 samples) had As concentrations greater than the screening value. The As content of the mine rock samples (median 14 mg/kg) was generally lower than the ore-grade samples (median 81 mg/kg).
  - Approximately 51% of samples from LP Central pit were enriched in As (n=1,688 samples). Lower proportions were observed for Viggo pit samples (27%, n=36 samples) and underground samples (35%, n=159 samples). Median As contents were higher for samples from LP Central pit (19 mg/kg) compared to samples from Viggo pit (4.1 mg/kg) and the underground (8.8 mg/kg).
  - Samples exhibiting As enrichment were observed for all key Project lithologies including a majority of Felsic Volcanic 2 (81% of samples) and Metasediment 2 (68% of samples), samples as well just under half of all Felsic Volcanic 1 samples (43%). Median As contents were higher for samples of Felsic Volcanic 2 (60 mg/kg) and Metasediment 2 (62 mg/kg) than samples from other lithologies (typically on the order of 5-20 mg/kg). Isolated instances of elevated As relative to the screening value were observed in trace lithologies.
- Concentrations of Se were greater than the screening value (0.5 mg/kg) in 31% of samples (n=1,200; Table 5.2-8). Selenium concentrations ranged from 0.1 mg/kg (the analytical detection limit) to 49 mg/kg (median 0.21 mg/kg; Tables B-4 and B-5, Appendix B).
  - Elevated Se was more frequently observed in ore-grade samples (occurring in 68% of samples) relative to mine rock samples (occurring in 27% of samples; Table 5.2-8). Approximately 33% of samples from LP Central pit, 8% of Viggo pit samples, and 20% of samples from the underground had concentrations greater than the Se screening value.
  - All key rock types had samples with elevated Se (Felsic Volcanic 1, Felsic Volcanic 2, Metasediment 2, Metasediment 3, Fragmental 2, and Basalt) for approximately 5-20% of samples.
  - Relationships between solid phase Se and S content suggested that Se substitution in pyrite may be present.
- Approximately 11% of samples (n=418) had Ag concentrations greater than the screening value (0.75 mg/kg; Table 5.2-8). Silver concentrations ranged from 0.007 mg/kg to 100 mg/kg (median 0.25 mg/kg) but were typically on the order of 0.15 to 0.5 mg/kg; Tables B-4 and B-5 of Appendix B). Silver enrichment was more frequently observed in ore-grade materials (44% of all samples; median 0.64 mg/kg) relative to mine rock samples (7% of samples; median 0.5%). Enrichment of Ag was observed in approximately 12% of samples from LP Central pit (n=389), 2% of samples from Viggo pit (n=2), and 6% of underground samples (n=27). Among key rock types, Ag enrichment was observed in samples of Felsic Volcanic 1 (13% of samples), Felsic Volcanic 2 (10% of samples), and Metasediment 2 (7% of samples), as well as one sample of Basalt, three samples of Fragmental 1 and four samples of Metasediment 3, as well as isolated instances of other lithologies.
- Concentrations of Cd were greater than the screening value (1.5 mg/kg) in 7% of drill core samples (Table 5.2-8). Cadmium concentrations ranged from 0.01 mg/kg (the analytical detection limit) to 450 mg/kg (median 0.070 mg/kg; Tables B-4 and B-5 of Appendix B). Values of Cd above the screening level was observed more frequently in ore-grade materials (18% of samples) relative to

mine rock samples (5% of samples). Levels above the screening concentration were observed in 7% of samples from LP Central pit (n=236) and 6% (n=28) of underground samples. No samples from Viggo pit had Cd content above the screening level. Similar proportions of samples with elevated Cd occurred among most key rock types, typically ranging from 2% to 9% of the samples in each lithology (Felsic Volcanic 1, Felsic Volcanic 2, Metasediment 2, Metasediment 3, Fragmental 1, Fragmental 2, and Basalt) A strong positive relationship between Cd content and Zn content was observed, especially for samples with >1 mg/kg of Zn, suggesting that Cd in these samples is likely associated with sphalerite.

- Concentrations of W were greater than the screening value (13 mg/kg) in 5% of samples, with concentrations ranging from 0.04 mg/kg to 1700 mg/kg (median 0.40 mg/kg; Table 5.2-8; Tables B-4 and B-5 of Appendix B). Higher W contents were observed more frequently in ore-grade samples (20% of samples) than mine rock samples (4% of samples). Approximately 6% of samples from LP Central pit, as well as one sample from Viggo pit, and 5% of samples from the underground were above the screening level. Elevated concentrations of W were primarily observed in samples Felsic Volcanic 1 and Felsic Volcanic 2 (7% of samples for both lithologies) isolated enriched samples were also observed for the Fragmental 1, Fragmental 2, Metasediment 2, and other lithologies. Solid phase W concentrations that were above screening values were attributed to the potential presence of scheelite (CaWO4); geological information indicates that scheelite was identified in LP Zone samples (Pfeiffer et al., 2023), however the presence of scheelite appeared to be limited in R-XRD testing of baseline samples.
- Isolated instances (i.e., <5% of samples tested samples) of metal concentrations greater than the screening values were observed for Zn (n=138), Mo (n=129), Pb (n=106), Cu (n=15), Sb (n=28), Ni (n=2) and Co (n=1; Table 5.2-8; Tables B-4 and B-5 of Appendix B). Values above the screening levels for these elements were primarily observed in Felsic Volcanic 1 and Felsic Volcanic 2 lithologies.
- Greater than 99% of the samples were below the 10 times crustal abundance screening value for Hg (0.85 mg/kg) and 90% of the overall dataset had Hg concentrations that were at or below the analytical detection limit (0.005 to 0.05 mg/kg). Less than 0.5% of the samples (n=19 of 3,885 samples) had Hg greater than the 10 times crustal abundance screening value. These isolated samples comprised Felsic Volcanic 1 and Felsic Volcanic 2 lithologies and had a median Hg content of 2.2 mg/kg. Over half (n=11 of 19) of these samples were ore-grade materials, and this group had a median sulphide content (2.0%) that was approximately one order of magnitude higher than the overall Project ML / ARD database (0.2% S), Felsic Volcanic 1 rock (median 0.28% S) and Felsic Volcanic 2 rock (median 0.13% S). Overall, this subset of samples appears to be atypical and non-representative of Project rock.

In general, higher metal concentrations were observed for samples with higher S contents, with broad trends in elemental content and S content were observed for Fe, As, Pb, Cd, Se, Zn, and Ag. Although Ag, Sb and Se concentrations were generally low (i.e., at or near the analytical detection limit) for most samples, higher concentrations of these elements were typically observed for samples with a higher S content relative to other samples. Several of these elements (including Cd, Pb, Se, and Zn) had stronger positive trends in samples with higher S contents, likely driven by the presence of sulphide minerals (such as sphalerite or galena), or substitution of these elements into pyrite.

Elemental content data were compared to S content on a molar basis for selected elements to assess the potential presence of metal sulphide minerals in the samples that could influence their acid generation potential. The findings of this assessment generally agreed with R-XRD data.

- Iron to S molar ratios aligned with the presence of pyrite and / or pyrrhotite in some samples (Figure 5.2-14). Higher Fe relative to S concentrations were observed for most samples, attributed to the partial dissolution of Fe-bearing oxides (e.g., hematite, magnetite) or some silicates (e.g., biotite, chlorite, amphiboles) in the aqua regia digest. These observations are consistent with the results of R-XRD testing, discussed further under Bulk Mineralogy (below).
- While As was identified to be elevated relative to screening values in 43% of samples, a comparison of As to S molar ratios indicated that the As content of the samples was lower than the S content for

most samples, as shown in Figure 5.2-15. This suggests that although arsenopyrite (FeAsS) has been identified in some of the Project rock, it does not appear to be the primary sulphide phase in the samples, and As may be present in other sulphide minerals (e.g., substituted in pyrite). Further detailed information on As mineralogy is presented in Section 5.3.

- A comparison of Zn and S content of the samples indicated that the Zn content of the samples was lower than the S content of most samples (Figure 5.2-16). However, a subset of samples comprising Felsic Volcanic 1, Felsic Volcanic 2, and Metasediment 2, had concurrently elevated Zn and S content, suggesting that sphalerite (ZnS) may be present among the tested samples. This was consistent with geological observations for the Project and the results of mineralogical testing (discussed further in Section 5.3).
- While chalcopyrite ($CuFeS_2$) and galena (PbS) have also been identified in geologic observations for the Project, concentrations of Pb and Cu were generally lower than the S content of the samples. This suggests that chalcopyrite and galena were not notably present in the tested samples.

Metal Leaching Assessment

Based on the results of solid phase elemental content, 228 samples were analyzed by SFE testing. The SFE leachates were compared to screening values to identify parameters of potential interest for metal leaching. The screening analysis included comparison of the SFE leachate chemistry to both PWQO and interim PWQO values. As previously described, the SFE test and screening approach is not a direct assessment of mine water quality and comparisons to screening criteria hold no regulatory significance.

SFE leachate results are tabulated in Tables B-7 and B-8 of Appendix B. Key parameters greater than the qualitative screening values are summarized in Table 5.2-9. Key observations for the SFE test are summarized below.

The pH of the SFE leachates was weakly acidic to alkaline, typically ranging from approximately pH 6.0 to 9.6 (median pH 8.0).

Sulphate concentrations were typically on the order of 2 to 10 mg/L (median 3.9 mg/L; Tables B-7 and B-8 of Appendix B). Eleven of the 228 leachates had relatively elevated sulphate concentrations, up to 230 mg/L. Most of these samples had elevated total S contents (2 to 8%), however, elevated sulphate concentrations in SFE leachates were not always observed for samples with higher total S contents (i.e., >1% total S).

Metal concentrations in the SFE leachates were typically below the qualitative screening values for most metals including Se, Mo, and Hg which had solid phase elemental content above screening values in isolated samples (Tables B-7 and B-8 of Appendix B). However, some metals had concentrations greater than screening values as outlined below:

- Concentrations of Al were greater than the interim PWQO screening value (0.075 mg/L) in 99% of samples tested by SFE (Table 5.2-9; Tables B-8 and B-9 of Appendix B). This is likely an artefact of the testing procedure due to the presence of colloidal Al and is unlikely to be observed under field conditions at neutral pH.
- SFE leachate concentrations of As were greater than the interim PWQO screening value (0.005 mg/L) in 65% of samples, and the PWQO screening value (0.1 mg/L) for 10% of samples (Table 5.2-9; Tables B-8 and B-9 of Appendix B). This included a majority (approximately 71%) of samples from the proposed LP Central pit and underground mine volumes. A smaller proportion of samples from the Viggo pit (39% of samples) were above the interim PWQO screening value and only one sample was above the PWQO value.
  - Concentrations of As in SFE leachates were variable and ranged from 0.00017 to 3.7 mg/L (median 0.025 mg/L). Samples from the LP Central pit and underground had slightly higher median concentrations of As in SFE leachates (0.016 mg/L and 0.013 mg/L, respectively) compared to samples from the Viggo pit (0.0025 mg/L). Samples of all key rock types had a majority of SFE leachates with As greater than the interim screening value (0.005 mg/L) except for Basalt, for which approximately half of the samples were above the interim PWQO screening value. A smaller proportion (on the order of 15% or less) were greater than the PWQO value (0.1 mg/L) for the key lithologies.

  - A relationship between solid phase As content and SFE leachate As concentration was observed, with higher solid phase As samples generally observed to show higher SFE As concentrations (Figure 5.2-17). The relationship between As release and As content has also been observed in kinetic testing (Sections 5.4 to 5.6), whereby higher steady state release rates of As have been observed for humidity cell test samples with higher solid phase As contents. Kinetic testing has demonstrated a relationship between As leaching rates and the As to S (As:S) molar ratio, which suggests that As host mineralogy is an important consideration for As leaching (discussed in detail in Section 5.3).

- Concentrations of V were greater than the interim PWQO screening value (0.006 mg/L) in 39% of the tested samples (Tables B-8 and B-9 of Appendix B), including 44% LP Central pit samples, 45% of underground samples and 15% of Viggo pit samples (15%). Elevated V was most frequently observed in samples of Basalt (65% of samples) and Metasediment 3 (53% of samples), but were also commonly observed in Metasediment 2, Felsic Volcanic 1, and Felsic Volcanic 2 samples. V concentrations were low overall and ranged from 0.00007 mg/L to 0.035 mg/L (median 0.0043 mg/L). In general, samples with a higher V content typically had higher V concentrations in SFE leachates, but this was not always observed.
  - Kinetic testing to date, including humidity cell and trickle leach column testing (Sections 5.4 and 5.5), has indicated that most Project rock is expected to leach V at concentrations below the interim PWQO value. One test, COL-7 (Basalt), produced leachates with vanadium concentrations above the interim PWQO value; however, Basalt comprises a very low percentage of Project rock (Table 5.2-1) and this sample had a very high solid phase V content (96th percentile or 180 mg/kg) that is not representative of V concentrations in the bulk of Project rock. Further, field testing has shown low leachate concentrations of V under field conditions where all measurements were below the interim PWQO value (see Section 5.6).
- Between 10% and 15% of samples had concentrations of P, Fe and Cr that were above PWQO or interim PWQO values (Table 5.2-9; Tables B-8 and B-9 of Appendix B). Approximately 20% of the samples from the LP Central pit, 11% of the samples from the underground mine and between 5% and 7% of samples from Viggo pit had concentrations of these elements above screening values. Most frequently, samples with concentrations above screening occurred in Fragmental 1, Fragmental 2 (iron only), Metasediment 2 and Metasediment 3.
- Less than 10% of samples had concentrations of Pb and Ag that were greater than PWQO and / or interim PWQO values. Specifically:
  - SFE leachates with Pb concentrations greater than the applied screening values comprised <20% of key rock types (Felsic Volcanic 1, Felsic Volcanic 2, Fragmental 1, Fragmental 2, Metasediment 2, and Metasediment 3) and occurred most commonly in samples from LP Central pit (16% of samples) and rarely in samples from underground (7%) and Viggo pit (2%). Concentrations of Pb concentrations ranged from 0.00005 mg/L to 0.069 mg/L (median 0.00009 mg/L) overall. In general, a trend was observed between samples with higher solid phase Pb concentration and higher Pb concentration in SFE leachates.
  - Concentrations of Ag were greater than the PWQO screening value (0.0001 mg/L) most commonly in samples from Felsic Volcanic 1 (12%), Felsic Volcanic 2 (6%) and Metasediment 2 (8%), and included 11% of LP Central pit samples, 2% of Viggo pit samples (n=1), and 5% of underground samples. Ag concentrations ranged from 0.00001 mg/L (the analytical detection limit) to 0.0012 mg/L (median 0.00005 mg/L) in the overall dataset.
- Isolated instances (i.e., <5% of the samples) of leachate concentrations greater than applicable PWQO and / or interim PWQO screening values were observed for Sb (n=8 samples), Co (n=5 samples), W (n=5 samples), Cu (n=3 samples), Cd (n=1 sample), Ni (n=2 samples), Zn (n=1 sample), and U (n=1 sample; Table 5.2-9; Tables B-8 and B-9 of Appendix B).

NAG leachate testing was undertaken to assess metal release under acidic conditions. Thirty-one samples were tested, and results are summarized below and in Table B-10 of Appendix B.

Results of NAG testing suggest that Ag, Al, As, B, Cd, Co, Cr, Cu, Fe, Mo, Ni, P, Pb, Se, Tl, U, V, W, and Zn are the most likely elements of potential interest under acidic conditions. Note that NAG leachate testing does not provide an assessment of the rates of metal release and kinetic tests are a more useful method for determining risks of metal leaching.

Bulk Mineralogy

Mineralogical identification using R-XRD was completed on 198 samples to assess their mineralogical composition including the presence of acid generating and acid neutralizing minerals. Results are presented in Table B-11 of Appendix B. Chemical formulae of the minerals discussed below are provided in Table 5.2-10. It is noted that R-XRD can identify minerals at concentrations down to fractions of a weight percent when suitable diffraction conditions exist. Key results are discussed below.

- Sulphide minerals were detected in 147 samples. Minerals identified generally included pyrite, pyrrhotite, sphalerite, and galena (Table B-11 of Appendix B).
  - Pyrite was identified in 124 samples and was the most common sulphide mineral identified by R-XRD Concentrations of pyrite ranged from 0.1 wt.% to 9.1 wt.% (typically 0.3 wt.% to 2 wt.%). In 70 of the 124 samples, pyrite was sulphide phase identified. For the remaining 54 samples containing pyrite, other sulphide phases were also present. Most commonly pyrite co-occurred with pyrrhotite (n=48 samples); however, other phases including sphalerite (n=13 samples), galena (n=2 samples), and marcasite (n=1 sample) were also present alongside pyrite.
  - Pyrrhotite was identified in 68 samples and typically ranged between 0.1 to 6.5 wt.% (median 2.5 wt.%). For 19 of these samples, pyrrhotite was the only sulphide phase present.
    - Pyrrhotite primarily occurred with pyrite but co-occurred with sphalerite in 9 samples. Pyrite and pyrrhotite were often present in similar amounts.
    - A few isolated samples in the dataset (n=9 of the 198 samples) had higher pyrrhotite contents, ranging from approximately 10 to 28 wt.%. The pyrrhotite content measured by R-XRD was supported by ABA test results for these samples. The majority of the samples where this occurred were from the Argillite lithology, which is a trace lithology (0.03%) relative to the overall mine volume. Such materials are not typical among the overall Project rock.
  - Sphalerite was identified in 17 samples and concentrations ranged from 0.1 wt.% to approximately 8 wt.% (typically 1 wt.%). Sphalerite was the only sulphide mineral identified in one sample (0.3 wt.%; DX450204, Felsic Volcanic 1). The other samples contained sphalerite and other sulphides including pyrite, pyrrhotite, and / or galena.
  - Galena was identified in two samples from the LP Central pit with concentrations of 0.3 and 0.6 wt.%. Galena was associated with other sulphide phases, including sphalerite and pyrite.
  - A comparison between R-XRD results (expressed as sulphide S) and ABA sulphide analysis (sulphide S by difference) indicated generally reasonable agreement between the two tests (Figure 5.2-18). In isolated instances (5 of 198 samples), differences of approximately 2-3% S were observed. This was attributed to subsample variability.
- Sulphate minerals were identified in two of the 198 samples.
  - Jarosite was detected in one underground sample of Basalt (DX550072) at a concentration of 0.6 wt.%. A comparison of sulphate from jarosite in this sample with sulphate measured by ABA indicated lower sulphate concentrations from ABA. There is uncertainty regarding the identification of jarosite in this sample as the identified concentration is below the generally reliable detection limit for R-XRD (several weight percent). Despite low levels of jarosite being measured, evidence of stored acidity (which can occur due to the presence of jarosite) was not identified for this sample. No other samples contained jarosite.
  - Gypsum was identified in one sample of ore-grade Felsic Volcanic 2 (DX450177) with a concentration of 0.6 wt.% (Table B-11 of Appendix B).

- Carbonate minerals were identified in 188 samples and included calcite, calcite-magnesian, dolomite, ankerite, dolomite-ankerite, siderite, and rhodochrosite. Ten samples with a generally low CarbNP content contained no detectable carbonates by R-XRD (Table B-11 of Appendix B).
  - Calcite was the dominant carbonate mineral in the samples and most contained calcite (n=146 samples) or magnesian calcite (n=48 samples). Where present, calcite (and magnesian calcite) concentrations typically ranged from 0.1 to approximately 4 wt.% in most samples.
  - Four samples had higher amounts of calcite (on the order of 30 to 49 wt.%); core photography provided by Great Bear Resources confirmed that all four samples were from sections of drill core with prevalent calcite veining. CarbNP contents of these samples calculated from R-XRD results (approximately 300-400 kg $CaCO_3$/t) agreed with CarbNP contents from ABA testing. As previously discussed, CarbNP contents of most samples tested by ABA ranged from 1 to 200 kg $CaCO_3$/t; these four isolated samples with a higher calcite content are not representative of the overall Project rock.
  - Dolomite was present in four of the samples and concentrations ranged from 0.1 wt.% to 0.8 wt.%. These dolomite-bearing samples also contained other carbonates including calcite, ankerite, and / or siderite.
  - Non-net neutralizing carbonate minerals were present at low levels in some samples, with concentrations ranging from approximately 0.1 to 1 wt.%. This included ankerite (30 samples), dolomite-ankerite (9 samples), and siderite (28 samples). These phases typically co-occurred with other carbonates including calcite.
  - Rhodochrosite was present in 7 of the samples with concentrations of 0.1 to 0.52 wt.%. These samples also contained calcite, siderite, and / or ankerite.
  - A comparison between R-XRD carbonate results (expressed as carbon) and TIC results from ABA testing generally indicated reasonable agreement between the two tests (Figure 5.2-19). At lower carbon concentrations, the carbon content of some samples was underestimated or overestimated by R-XRD relative to ABA testing. This difference was attributed to the low sensitivity of R-XRD at lower concentrations.

The following additional observations are provided from the R-XRD results:

- Feldspars identified in the samples included K-feldspar (as microcline, orthoclase, and unspecified K-feldspar) and plagioclase (as albite, anorthite, and unspecified plagioclase) (Table B-11 of Appendix B).
  - Contents of K-feldspar ranged from 0.1 wt.% to approximately 22%.
  - Plagioclase contents ranged from 0.4 to 73 wt.%. In all mine areas (LP Central pit, Viggo pit, and the underground), plagioclase (albite) was the most dominant form of feldspar. Concentrations of anorthite were typically much lower than concentrations of albite in the tested samples.
- Quartz was present in all samples, with concentrations ranging from 1 to 82 wt.%. Other oxide minerals including ilmenite, magnetite, rutile, goethite, titanite, and hematite were variably present in generally low amounts (<5 wt.%; Table B-11 of Appendix B).
- Phyllosilicates were identified in the samples including chlorite, clinochlore, muscovite, illite, biotite, talc, phlogopite, kaolinite, biotite-phlogopite, and petalite. Most samples contained chlorite, muscovite, and biotite, with lesser quantities of the other phyllosilicate minerals identified. Chlorite contents in the samples ranged up to 12 wt.%. Muscovite contents in the samples were generally on the order of 3 to 12 wt.% with a few samples ranging up to 53 wt.%. Biotite contents in the samples ranged from 0.2 to 25 wt.% with most samples on the order of 5 wt.%. Kaolinite was present in 19 samples up to approximately 1 wt.%. Clinochlore occurred in 40 samples, with concentrations on the order of 1 to 3 wt.% in most samples. Other phyllosilicate phases, including talc, phlogopite, and petalite, occurred in isolated samples.

- Amphibole phases identified included actinolite, cummingtonite, hornblende, and magnesiohornblende. Amphiboles were most abundant in Basalt samples, though some higher concentrations were found in Felsic Volcanic 1 samples as well. These higher concentrations were generally found in actinolite (on the order of 20 to 60 wt.%). Actinolite, cummingtonite, hornblende, and magnesiohornblende were variably present in samples of other lithologies including isolated samples of Felsic Volcanic and Metasediment rock types.
- Pyroxene (diopside) was identified in 91 samples up to a concentration of approximately 6 wt.% and were most commonly present among the Felsic Volcanic, Metasediment, and Fragmental rock types (Table B-11 of Appendix B).
- Garnet in the form of almandine was present in 30 of the samples with concentrations ranging from 0.2 to 15 wt.%. Pyrope was present in 4 samples up to 13 wt.% and spessartine was present in 2 samples with concentrations up to 6 wt.%.
- Tourmaline (dravite) was present in 7 samples ranging from 0.7 to 11 wt.% (Table B-11 of Appendix B).
- Low levels of scheelite (0.5 wt.%) were identified in one sample (Table B-11 of Appendix B).
- Phosphates (apatite) were identified in 11 samples with concentrations ranging from 0.3 to 0.8 wt.% (Table B-11 of Appendix B).
- Sorosilicates identified in the samples included epidote and clinozoisite (Table B-11 of Appendix B). Epidote concentrations ranged from 0.5 to 8 wt.% in nine samples. Clinozoisite concentrations ranged from 0.7 to 4 wt.% in 18 samples.

5.2.6 KEY FINDINGS

Acid Generation Potential

- Samples from LP Central pit had higher median S content (0.73%) than samples from the Viggo pit (0.26%) or underground mine volume (0.25%). The range of S contents for samples from the open pits and the underground were similar, with concentrations ranging from below the analytical detection limit (0.01%) to approximately 10%. Higher median S contents were observed in samples of ore-grade materials (1.3%) compared to mine rock (0.39%); however, numerous mine rock samples had S contents that were similar to, or even higher than, the ore-grade samples. Median S contents were highest (approximately 0.5 to 0.7%) among samples of Felsic Volcanic 1 and Felsic Volcanic 2 samples, which represent the main rock type in the mine volume. Concentrations of S were lower (median values ranging from approximately 0.15 to 0.4%) for samples of other rock types including Metasediment 2, Metasediment 3, Fragmental 1, and Basalt. Relatively low (0.06%) median S contents were observed for samples of Fragmental 2.
- ABA test results indicated that sulphide was generally the primary S species in the samples. This observation is supported by the findings of R-XRD and detailed mineralogy (Section 5.3), which indicated that S was primarily present as the sulphide minerals pyrite and pyrrhotite, with minor to trace amounts of other sulphides, primarily including sphalerite and galena. Non-acid generating sulphide minerals comprised a small proportion of the sulphides in the samples overall (generally representing <2% of the total S content where present).
- Samples had a median CarbNP content of 11 kg $CaCO_3$/t, with most samples having CarbNP contents between 1 and 200 kg $CaCO_3$/t. CarbNP was typically similar to or lower than Modified NP, suggesting most of the neutralization capacity in the samples was present as carbonate minerals. This agrees with the results of R-XRD testing that demonstrated calcite was the primary contributor to neutralization capacity. Non-net neutralizing carbonates (e.g., siderite, ankerite) were present at low abundances in isolated samples and typically co-occurred with calcite. Some samples of Felsic Volcanic 1, Felsic Volcanic 2, Fragmental 1, Fragmental 2, Metasediment 2, or Metasediment 3 contained no detectable CarbNP and low levels of Modified NP. Higher CarbNP contents (median 49 kg $CaCO_3$/t) were observed for samples of Basalt.

- Overall, 80% of drill core samples were classified as PAG by a CarbNPR threshold of 2, including 78% of mine rock samples and 94% of ore-grade samples. This included a majority of samples from the open pits and underground with the highest proportion of PAG samples in the LP Central pit. A majority of Felsic Volcanic 1, Felsic Volcanic 2, Fragmental 1, Metasediment 2, Metasediment 3, and Argillite samples were classified as PAG. Basalt and Fragmental 2 samples were primarily classified as NPAG. Lag times for PAG samples will be confirmed by kinetic testing which is underway.
- NAG pH test results generally supported the results of ABA testing, however, NAG pH test results indicated that some samples with a lower S content (S ≤0.15%) may be NPAG despite having a CarbNPR ≤2. To date, kinetic test results are supportive of this threshold value (Section 5.4.5).

Elemental Content and Metal Leaching Assessment

- The results of elemental screening analysis identified that solid phase concentrations of most metals were low relative to 10 times average crustal abundance values. Solid phase concentrations of some elements were greater than their qualitative screening values for some samples including As (48%), Se (31%), Ag (11%), Cd (7%), and W (5%). Approximately 3 to 4% of samples had concentrations of either Zn, Mo, and / or Pb above the screening criteria. Few samples (approximately ≤0.5%) were above the criteria for the metals Cu, Sb, Ni, and Co.
- Greater than 99% of the samples were below the 10 times crustal abundance screening value for Hg (0.85 mg/kg) and 90% of the overall dataset had Hg concentrations that were at or below the analytical detection limit (0.005 to 0.05 mg/kg). Less than 0.5% of the samples (n=19 of 3,885 samples) had Hg greater than the 10 times crustal abundance screening value; most of these samples were ore-grade materials.
- SFE leachate results indicated that As may be a parameter of potential interest for metal leaching under neutral leaching conditions, with 65% of samples being above the interim PWQO screening value. A small subset of the samples (10%) had concentrations of As above the PWQO value. Further assessment of metal leaching has been carried out (Section 5.3), along with kinetic testing (Sections 5.4 to 5.6). Other elements with isolated enriched solid phase elemental contents were not considered to be a risk for metal leaching based on SFE concentrations.
- Some metals were observed to have concentrations above PWQO screening values in SFE leachates including V (39% of samples), P (13% of samples), Fe (15% of samples), Cr (11% of samples), Pb (8% of samples), and Ag (6% of samples). Isolated samples (<5% of the dataset) had concentrations of Sb, Co, W, Cd Ni, Cu, Zn, and U above the screening values used. These parameters were included in subsequent metal leaching studies (i.e., kinetic testing). Metal release rates are discussed further in Sections 5.4 to 5.6.
- NAG leachate results indicated that Ag, Al, As, B, Cd, Co, Cr, Cu, Fe, Mo, Ni, P, Pb, Se, Tl, U, V, W, and Zn are the most likely elements of potential interest under acidic leaching.

Table 5.2-1: Relative Abundances of Rock Types - Open Pits and Underground

Lithology	Relative Abundance [1]		
	LP Central Pit	Viggo Pit	Underground
Felsic Volcanic 1	73%	38%	41%
Felsic Volcanic 2	12%	12%	39%
Fragmental 1	-- [2]	24%	0.009%
Fragmental 2	0.1%	5%	1%
Metasediment 2	13%	9%	11%
Metasediment 3	2%	8%	5%
Basalt	-- [2]	0.3%	3%
Argillite	-- [2]	-- [2]	0.03%
Other Rock Types [3]	0.006%	3%	0.48%

Notes:

1 Abundances were calculated from the Project block model.

2 Indicates no volume of the rock type is present in the block model files.

3 Other lithologies include Rhyolite, Ultramafic, Quartz, Sericite Schist, Andalusite Schist, Intrusive Breccia, Metasediment 1, Calcite Vein, and Felsic Fragmental.

Table 5.2-2: Drill Core Sample Summary

Group	Number of Mine Rock Samples	Number of Ore-Grade Samples	Total Samples
All Samples	3,495	390	3,885
By Area			
LP Central pit	2,940	361	3,301
Viggo Pit	125	6	131
Underground	430	23	453

Other lithologies include Rhyolite, Ultramafic, Quartz, Sericite Schist, Andalusite Schist, Intrusive Breccia, Metasediment 1, Calcite Vein, and Felsic Fragmental.
Classification as mine rock or ore-grade materials was based on gold content.

1 Including total S by Leco furnace, sulphate S by HCl leach, sulphide S by difference, Modified Sobek NP based on MEND (1991) which is an update to the 1989 Lawrence Modified NP method, TC by Leco furnace, and TIC by HCl leach and Leco furnace.

2 Additional cycles of NAG testing completed as required based on guidance in AMIRA (2002).

Table 5.2-4: Summary of ABA and Elemental Content Duplicate Tests

Key Solid Phase Parameters	Number of Pulp Duplicate Analyses	Number of Prep Duplicate Analyses
Total S	157	30
Sulphate S	107	30
Modified NP	112	30
TIC	125	30
TC	133	30
Aqua Regia ICP-MS Metals	155	28
Four acid ICP-MS Metals	151	26

Notes:

Pulp duplicates represent two analyses performed on splits of the same pulverized material. Pulp duplicates include samples initially run at SGS Lakefield and re-analyzed at Global ARD as well as samples initially run at Global ARD that were analyzed in duplicate as part of routine QA / QC practices.

Prep duplicates represent two analyses performed on splits from the same parent sample that were pulverized separately.

Notes:
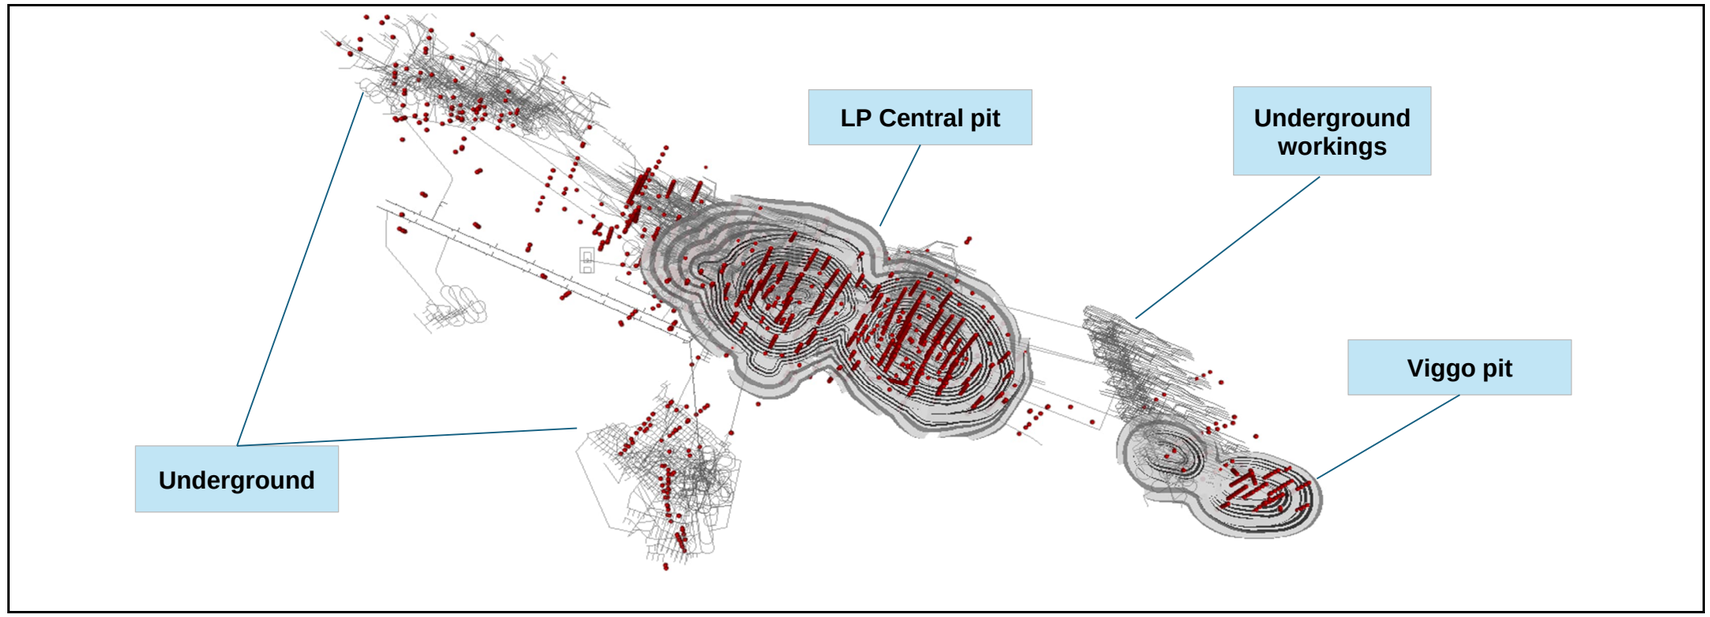
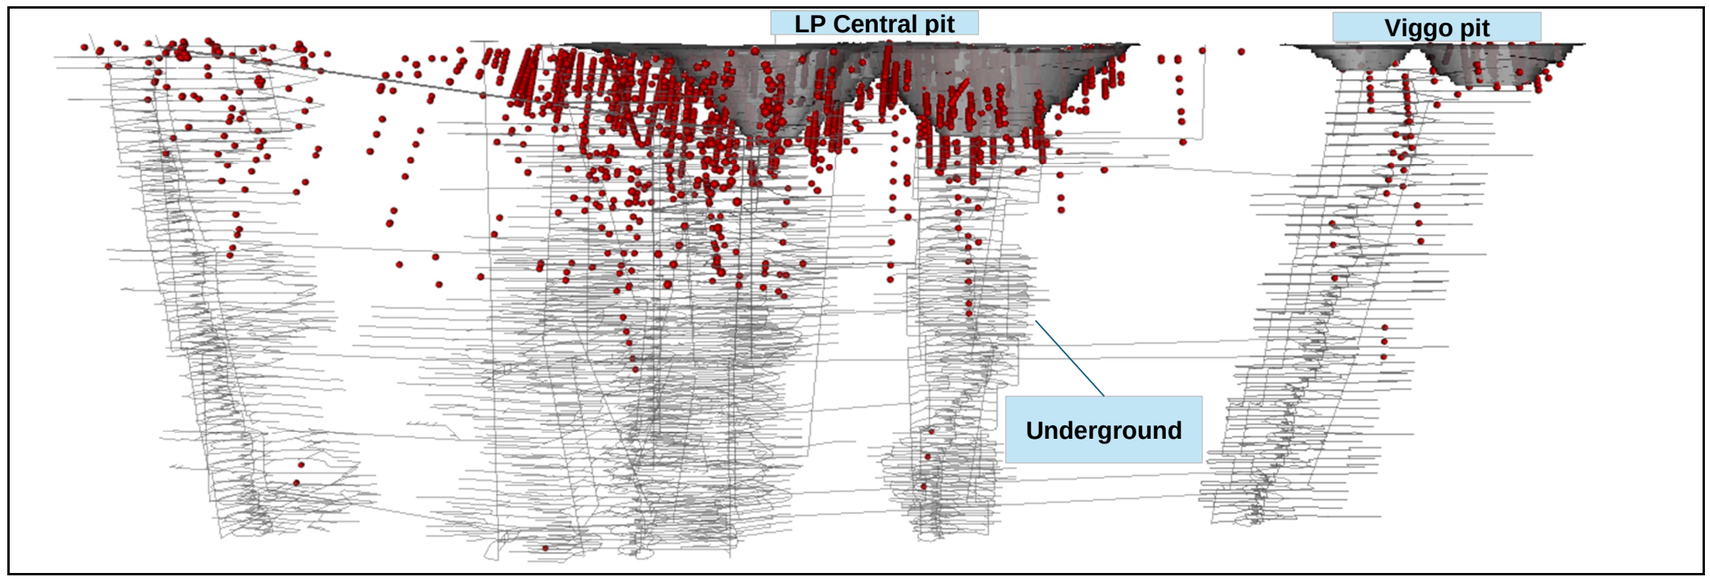
Samples with dashed (--) notation indicate no screening value.
Classification as mine rock or ore-grade materials was based on gold content.
Other lithologies include Rhyolite, Ultramafic, Quartz, Sericite Schist, Andalusite Schist, Intrusive Breccia, Metasediment 1, Calcite Vein, and Felsic Fragmental.
Screening values are for qualitative assessment only and hold no regulatory significance.

Table 5.2-10: Chemical Formulae of Phases Identified in R-XRD Testing

Mineral Group	Mineral	Chemical Formula
Sulphides	Pyrite	FeS_2
	Marcasite	FeS_2
	Pyrrhotite	Fe_7S_8
	Sphalerite	ZnS
	Galena	PbS
Sulphates	Jarosite	$KFe_3(SO_4)_2(OH)_6$
	Gypsum	$CaSO_4\ 2H_2O$
Carbonates	Calcite	$CaCO_3$
	Calcite magnesian	$(Ca,Mg)CO_3$
	Dolomite	$CaMg(CO_3)_2$
	Ankerite	$CaFe(CO_3)_2$
	Dolomite - Ankerite	$CaMg(CO_3)_1 – Ca(Fe^{2+},Mg,Mn)(CO_3)_2$
	Siderite	$FeCO_3$
	Rhodochrosite	$MnCO_3$
Feldspars	Potassium Feldspar (including microcline, orthoclase, and unspecified)	$KAlSi_3O_8$
	Albite	$NaAlSi_3O_8$
	Anorthite	$CaAl_2Si_2O_8$
	Plagioclase	$(NaSi,CaAl)AlSi_2O_8$
Oxides	Ilmenite	$FeTiO_3$
	Quartz	SiO_2
	Magnetite	Fe_3O_4
	Rutile	TiO_2
	Goethite	$\alpha FeO{\cdot}OH$
	Titanite	$CaTiSiO_5$
	Hematite	Fe_2O_3
Phyllosilicates	Chlorite	$(Fe,(Mg,Mn)_5,Al)(Si_3Al)O_{10}(OH)_8$
	Clinochlore	$(Mg,Fe^{2+})_5Al(Si_3Al)O_{10}(OH)_8$
	Muscovite	$KAl_2(AlSi_3O_{10})(OH)_2$
	Illite – Muscovite 2M1	$\sim K_{0.65}Al_{2.0}(Al_{0.65}Si_{3.35}O_{10})(OH)_2$
	Biotite	$K(Mg,Fe)_3(AlSi_3O_{10})(OH)_2$
	Talc	$Mg_3Si_4O_{10}(OH)_2$
	Phlogopite	$KMg_3(AlSi_3O_{10})(OH)_2$
	Kaolinite	$Al_2Si_2O_5(OH)_4$
	Biotite-Phlogopite	$K(Mg,Fe)_3(AlSi_3O_{10})(OH)_2$
	Petalite	$LiAlSi_4O_{10}$
Amphiboles	Actinolite	$Ca_2(Mg,Fe)_5Si_8O_{22}(OH)_2$
	Cummingtonite	$(Mg,Fe)_7Si_8O_{22}(OH)_2$
	Amphibole (actinolite; cummingtonite)	$AB_2C_5((Si,Al,Ti)_8O_{22})(OH,F,Cl,O)_2$
		A = Na, K, Ca, Pb^{2+}
		B = Li, Na, Mg, Fe^{2+}, Mn^{2+}, Ca
		C = Li, Na, Mg, Fe^{2+}, Mn^{2+}, Zn, Co, Ni, Al, Fe^{3+}, Cr^{3+}, Mn^{3+}, V^{3+}, Ti, Zr
	Hornblende	$(Ca,Na)_{2\text{-}3}(Mg,Fe,Al)_5Si_6(Si,Al)_2O_{22}(OH)_2$
	Magnesiohornblende	$Ca_2(Mg,Fe)_4Al(Si_7Al)O_{22}(OH,F)_2$
Pyroxenes	Diopside	$CaMgSi_2O_6$
Garnets	Almandine	$Fe^{2+}{}_3Al_2(SiO_4)_3$
	Spessartine	$Mn_3Al_2Si_3O_{12}$
	Pyrope	$Mg_3Al_2Si_3O_{12}$
Tungstates	Scheelite	$CaWO_4$
Tourmalines	Dravite	$NaMg_3Al_6(BO_3)_3Si_6O_{18}(OH)_4$
Phosphates	Apatite	$Ca_5(PO_4)_3(F,Cl,OH)$
Sorosilicates	Epidote	$Ca_2(Al,Fe)Al_2O(SiO_4)(Si_2O_7)(OH)$
	Clinozoisite	$Ca_2Al_3(SiO_4)_3(OH)$





Notes

LP Central pit design based on the files Surface_LP-NOV_10x5x10_1700-MII_10_No-Susex_Limited and pitdsgn_1400_PF85_Pits no topo_tr. Viggo pit design was based on string_topo_intersection_1400_pf100_viggo_10025_v12_250604. All files provided by Great Bear Resources.

Underground design based on the file GBP - Total Mine Dev Solids 2023120 provided by Great Bear Resources. Deeper levels of the underground mine will be developed later in the Project and sample coverage in these areas will be supplemented as additional drilling is conducted.

Notes

Total Sulphur measured by Leco furnace

Sulphide Sulphur calculated by difference (Total S measured by Leco Analyzer - Sulphate S measured by HCl Leach)

The samples listed as 'known to contain pyrrhotite represent the samples analyzed by XRD where pyrrhotite was identified. Of the 933 samples shown, 198 were tested by XRD and it is expected that additional samples shown in the figures also contain pyrrhotite based on the test response.

Classification as mine rock or ore-grade materials was based on gold content.

Notes

CarbNPR clculated as CarbNP/MPA.

NAG pH by single addition NAG test. Samples classified as PAG (NPR 2) with NAG pH >4.5 sometimes contained >1% sulphur; higher NAG pH values may result from incomplete oxidation in these samples (see text).

A CarbNPR threshold of 2 was used for separating PAG and NPAG samples. This value is generally accepted as industry best practice in the absence of a site-specific geochemical threshold.

Classification as mine rock or ore-grade materials was based on gold content.

Notes

Total C from R-XRD based on the sum of carbonate species detected during R-XRD testing.

TIC from ABA testing measured by HCl leach and Leco furnace.

R-XRD concentrations are generally reliable at concentrations >0.5%. Detection limitis generally range from 0.2-0.5% depending on crystallinity.

Classification as mine rock or ore-grade materials was based on gold content.

5.3 DETAILED MINERALOGY

5.3.1 *PROGRAM OVERVIEW*

Mineralogy is fundamental to the understanding of the physical and geochemical stability and relative weathering rates of geological materials under different weathering conditions (MEND 2009). The detailed mineralogy program for the Project included 65 samples selected to be representative of key Project rock types as shown in Table 5.3-1. The samples represent the range of geochemical characteristics observed in the static tests for both mine rock and ore-grade materials.

The objectives of the detailed mineralogy study were to establish the range of host minerals for As and other elements of interest and confirm the sulphide, carbonate, and overall mineralogy of the Project rock as expressed in the representative column and humidity cell samples. The work expands on and supports static testing (Section 5.2) and provides detailed mineralogical information to support humidity cell (Section 5.4), column leaching (Section 5.5) and FLB studies (Section 5.6). This section contains data reported up to March 2025.

In addition to understanding the distribution of potential elements of environmental interest in the column and humidity cell programs, knowledge of the different sulphide forms and the understanding of minor elements present within the sulphide minerals can support interpretation of metal leaching observations.

5.3.2 TEST SAMPLES

In total, 65 samples were selected for detailed mineralogy and kinetic tests. Fifty-three samples were analyzed in early 2024 and 12 samples were analyzed in late 2024 (Appendix C1). Samples were identified to represent key rock types in the mine volume (Table 5.3-1). Four of the detailed mineralogy samples (e.g., FV1: DX450232 and Basalt: DX450022, DX450113, DX550101) were used for both column and humidity cell testing.

The detailed mineralogy program included all samples selected for humidity cell and column tests. The samples covered the major rock types expected for the Project and a wide range of PAG and NPAG materials generally covering the range of metal contents, sulphide content and NP observed for the applicable static data (Table 5.3-2).

Samples were selected from available representative sample splits from static testing and included samples with sufficient material for the humidity cell and column kinetic tests and corresponding detailed mineralogy analysis.

Most samples were available as coarse rejects from previous work at SGS in Lakefield, Ontario. The material represented a crush size of <9.5 mm or <6.3 mm and 150 g was further crushed to a P80 (80% passing) 150 µm after which a polished section prepared for mineralogical analysis. For eight of the humidity cell samples (HC-3, HC-4, HC-6, HC-7, HC-13, HC-15, HC-22 and HC-26) only pulverized (80% passing 75 µm) assay pulp material was available for the mineralogy work after humidity cell preparation. For these samples polished sections were prepared directly from the material received. For each sample a 0.2 to 0.5 g split was pulverized to 75 µm and was submitted for representative chemical analysis.

5.3.3 METHODS OF ANALYSIS

Quantitative mineralogy analyses were completed by SGS Lakefield under the direction of WSP. Additional supporting microprobe work was conducted at Queen's University in Kingston, Ontario under the direction of SGS Lakefield and WSP. The work was conducted in two stages including 53 samples analyzed in early 2024 and 12 samples analyzed in late 2024 (Appendix C1).

Each petrographic polished section was subjected to quantitative mineralogy by QEMSCAN including analysis of major and minor mineral constituents. EMPA was also included for selected target minerals to confirm mineral identities and identify minor element content of the primary sulphide minerals identified by QEMSCAN. Geochemical analysis was included to support the quantitative

mineralogy by providing a mass balance check for major constituents. Analytical method descriptions are provided in the subsections below and in Section 4.

Quantitative Mineralogy

QEMSCAN is configured to measure mineralogical variability based on chemistry at the micrometer-scale. The mode of QEMSCAN analysis used for this Project (Appendix C1) was Particle Mapping Analysis. Particle Mapping Analysis is a two-dimensional mapping analysis aimed at resolving liberation and locking characteristics of a generic set of particles. A pre-defined number of particles are mapped at a point spacing selected to spatially resolve and describe mineral textures and associations.

QEMSCAN utilizes both the back scattered electron signal intensity, as well as an energy dispersive X-ray spectral signal at each measurement point and makes no simplification or assumption of homogeneity based on the backscatter electron intensity. The spectral signal is used to assign mineral identities to each measurement point by comparing the spectrum against a mineral species identification program or database.

The raw data as collected by the instrument is extracted, reviewed for quality, and processed offline using the iExplorer software and reported in a standardized format. Processing includes textural and chemical refining of the data and classification into categories to extract appropriate mineralogical data for the program.

The work (Appendix C1) also documents simulated grain-size of the carbonate and sulphide minerals analyzed as well as liberation information gathered during the QEMSCAN processing. The information is available to consult but was not the focus of this study. Additional size reduction of the samples with a focus on mineral identification means the mineral liberation observed will no longer represent the coarser column and humidity cell materials.

Electron Microprobe Analysis

EMPA was conducted using a JEOL JXA-8230 probe in point analysis mode with calibration to reference standards (Appendix C1). Most samples underwent EMPA analysis for target minerals identified in QEMSCAN analysis. Some samples were not analyzed due to a low abundance of minerals of interest. Spot analysis targeted by the operator included quantification of the major elements for each mineral and selected minor elements. A lower limit of detection was determined for minor elements in the analyses using the 3-sigma method.

The sulphide and sulpharsenide minerals selected for analysis and the minor elements quantified for each are shown in Table 5.3-3.

In addition to the minerals summarized in Table 5.3-3, the following additional minerals were analyzed by EMPA:

- Pentlandite $(Fe,Ni)_9S_8$ was detected as a minor component of the sulphide fraction in a number of samples using QEMSCAN. A few of these samples were targeted for analysis by EMPA, but pentlandite targets were not located by the operator and therefore no analyses for pentlandite are currently available.
- The arsenide loellingite ($FeAs_2$) was also detected by two-point analysis in the EMPA data in one sample and analysis of Co, Ni, Sb, and Se (n=1; COL-11 / HC-23) was completed. It is noted that loellingite was not detected in this sample by QEMSCAN.
- EMPA analyses were also completed on two relatively abundant Ca-Al-Silicates (e.g., amphibole and garnet) in several Basalt samples to confirm mineral composition.

The element deportment for the sulphide and sulpharsenide mineral fraction of each sample was calculated based on the mineral mass of each phase from QEMSCAN and the average composition of each phase from the EMPA data.

Geochemical Analysis

Geochemical analysis was conducted for the 65 samples. The geochemical analysis was completed to provide a reference and check on the element totals determined by QEMSCAN and associated element deportment totals. Analytical methods included:

- Total S and TC analysis by combustion using a carbon / sulphur analyzer.

- Whole rock analysis of major elements by borate fusion X-ray Fluorescence.
- Four acid digest to quantify major and trace elements. Quantification was by ICP-OES for the first stage of work and ICP-MS for the second stage of analysis. Four acid digest was completed for quantification of total element content for comparison to QEMSCAN results.
- Aqua-regia digest and quantification by ICP-MS was also included for the second stage of analyses for consistency with interim work at the time and for completeness. Results were consistent with and did not materially affect or contribute to this program.

Whole rock analysis included quantification as major oxides: SiO_2, Al_2O_3, Fe_2O_3, MgO, CaO, Na_2O, K_2O, P_2O_5, MnO, TiO_2, Cr_2O_3, V_2O_5 and LOI. Four acid ICP-OES analysis included quantification of: As, Ag, Ba, Be, Bi, Cd, Co, Cu, Li, Mo, Ni, Pb, Sb, Se, Sn, Sr, Tl, Y, Zn. Aqua regia and four acid ICP-MS analysis included quantification of: Hg (aqua regia only), Ag, As, Al, Ba, B (aqua regia only), Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mn, Mo, Na, Ni, P, Pb, S, Sb, Se, Sn, Sr, Ti, Th, Tl, U, V, W, Y, Zn, and Zr. Mercury and B were only provided by aqua regia digestion and ICP-MS since this lower temperature digestion allows Hg and B to be non-volatile under the analytical conditions.

The above-described work represents direct analysis of the sample splits prepared for the detailed mineralogy and kinetic test work. Each sample is also represented by static test work (Section 5.2) applicable to that sample that will generally include at least ABA, element content by aqua regia and four acid digestion and ICP-MS. In addition, some samples included SFE, R-XRD, NAG pH and NAG leachate. The static four acid digest results were considered the reference values for interpretation of the detailed mineralogy and metal leaching results.

5.3.4 DATA ANALYSIS AND INTERPRETATION

The detailed mineralogical assessment focused on As, Cd, Co, Cu, Mo, Ni, Pb, Sb, Se and Zn as they are the principal elements observed to be associated with the sulphide fraction of the samples and have regulatory water quality guidelines that are potentially applicable to the Project. Iron, which is the predominant element in the sulphide minerals, was also considered since it is potentially relevant in metal release from oxidizing sulphide minerals and when oxidized also produces iron oxyhydroxide surfaces capable of sorbing As and other minor / trace elements.

Other elements of interest identified in the static program (Section 5.2.5) including V, P, Cr, W and U may be present in relatively low abundance and likely without association to the sulphide fraction of the samples. In addition, none of these elements were greater than the applicable screening values in column studies (Section 5.5).

Mercury is a potential element of interest from an environmental perspective. However, static test work has shown that solid phase mercury concentrations are very low with 75th percentile concentrations below the analytical detection limits (<0.05 and <0.005 mg/kg) and was not expected to be well resolved in this mineralogy study. In addition, no SFE leachates in static testing had concentrations greater than the PWQO screening value (0.0002 mg/L). Mercury was also not identified as a neutral metal leaching concern in column and humidity cell tests. Steady-state concentrations in column leachates were consistently below the screening value and humidity cell release rates were similarly low and based on concentrations consistently below the screening value. Consistent with the low overall concentrations, Hg was not observed as a discrete mineral phase in the QEMSCAN analysis or as a minor element in EMPA analysis of sulphide minerals.

QEMSCAN and EMPA

SGS Lakefield detected numerous mineral phases in the suite of samples and a mineral list was developed with the iExplorer processing software. Simulated element assays were calculated from the QEMSCAN data and compared to the applicable chemical reference analysis. Deviation between the calculated QEMSCAN assays and actual assays may occur due to the solid solution chemistry of some minerals.

A proposed number of EMPA analyses for target minerals (Table 5.3-4) in each polished section was roughly scaled from QEMSCAN mineral abundance by SGS Lakefield in consultation with WSP. The number of proposed analyses per section was identified to the analyzing laboratory (Queen's University). The actual numbers of analyses completed approached the target values, but in a few cases were limited by the ability of the operator to locate sufficient targets especially for low abundance minerals in a given section. EMPA quantification of relevant minor elements in each

sulphide mineral was determined by the operator and confirmed by inspection of X-ray spectra at the time of analysis.

The QEMSCAN sulphide mineral modal distributions along with the EMPA data were used to determine the elemental deportment by sulphide mineral for each sample. Elemental deportment was calculated for S, Fe, As, Cd, Co, Cu, Mo, Pb, Ni, and Zn. Since probe data was not available for pentlandite, an assumed stoichiometry for this mineral ($Fe_{4.5}Ni_{4.5}S_8$) was applied.

For some minerals a low and high concentration range of some minor elements were observed. For these situations, a threshold approach was applied where a higher concentration was assigned when the average concentration of that element was above a prescribed threshold for a given mineral. The high and low concentration EMPA averages were applied to the selected samples as shown in Table 5.3-5.

5.3.5 QUALITY ASSURANCE AND QUALITY CONTROL

Upon receipt, laboratory data quality was reviewed. QA / QC protocols included a comparison of element of interest concentrations that were determined among the different analytical programs for the same samples. This included the four acid ICP-OES / MS results from the detailed mineralogy program, the four acid ICP-MS analysis from static testing, and the QEMSCAN / EMPA (deportment) totals. Results were in generally good agreement. Specific variance where it was noted is discussed for the applicable results (Section 5.3.8).

A comparison of the ABA results from static testing and corresponding speciated sulphide and carbonate QEMSCAN results was included as well as a comparison of mineralogy by R-XRD and QEMSCAN. The ABA and QEMSCAN results were generally in agreement, however, low levels of sulphate sulphur (assumed to be present as gypsum / anhydrite) was detected in all samples in QEMSCAN which contrasted distinctly with sulphate determinations by ABA at notably higher concentrations and is described in Section 5.3.8. The R-XRD and QEMSCAN results were similar overall for major minerals identified (generally greater than 10%) and a discussion of the results from these two programs are also provided in Section 5.3.8.

5.3.6 RESULTS - QUANTITATIVE MINERALOGY AND EMPA

Detailed mineralogy and EMPA results for the 65 samples are described in the following subsections with supporting information provided in Appendix C.

QEMSCAN

The overall modal mineralogy of the samples organized by lithology are summarized below and in Figure 5.3-1 to Figure 5.3-5:

- The sulphide mineral content varied from trace to over 10 wt.% in a few samples and included primarily pyrite (0.02 to 11.5 wt.%) and sometimes pyrite and pyrrhotite (0 to 16.8 wt.%). Other sulphide minerals including arsenopyrite (FeAsS), chalcopyrite ($CuFeS_2$), gersdorffite-cobaltite (Fe,Ni,Co)AsS, sphalerite (Fe,Zn)S, and / or galena (PbS) were observed at 1 wt.% to a few wt.% in one or more samples. Molybdenite (MoS_2) and pentlandite ($(Fe,Ni)_9S_8$) were not detected in the majority of samples. When detected they were at trace concentrations (<0.1 wt.%) except for pentlandite for a single Metasediment 2 sample (HC-15; 0.7 wt.%). [4]
- Notably lower total sulphide mineral content was observed for the Metasediment 3 (<0.73 wt.%; Figure 5.3-3), Basalt (<1.4 wt.%; Figure 5.3-4) and Fragmental 2 samples (<1.1 wt.%; Figure 5.3-) which is consistent with the observed generally lower S contents of these units. The highest pyrite (11.5 wt.%) and pyrrhotite (16.8%) content were observed in Argillite samples HC-26 and COL-1, respectively (Figure 5.3-3). Sulphide mineral content of the samples is further discussed below in relation to element deportment (Section 5.3.7).

[4] Pentlandite in this Metasediment 2 sample represented 5% of the sulphide fraction by mass and two lower sulphur content Felsic Volcanic 1 samples (HC-7 and COL 29) had low pentlandite concentrations that represented around 1% of the total sulphide content with the rest of samples having low or undetectable amounts.

- Calcite was the primary carbonate mineral observed among all samples (Figure 5.3-1 to Figure 5.3-5) ranging from 0.02 to 11 wt.% with dolomite / ankerite generally observed in trace amounts ranging from 0 to 0.8 wt.%. Except for Basalt, the calcite content of all lithologies was variable and was often observed at only trace concentrations. Basalt samples (Figure 5.3-4) contained higher calcite content (range 2.2 to 11 wt.%).
- For broader context, the principal mineralogy of Felsic Volcanic and Metasediment lithologies contained quartz, plagioclase (albite / oligoclase), and sericite / muscovite (Figure 5.3-1 to Figure 5.3-3). However, Metasediment 2 samples (Figure 5.3-3) generally contained a higher abundance of biotite (6.4 to 31 wt.%) and sometimes more chlorite (0.80 to 18.3 wt.%). More calcic plagioclase forms (e.g., labradorite and bytownite / anorthite) were detected at relatively low concentrations in most samples compared to the more sodic albite / oligoclase. A few samples, primarily from Felsic Volcanic 1, had calcic plagioclase in greater abundance than the sodic form.
- Argillite samples also primarily contained quartz and plagioclase (albite / oligoclase; Figure 5.3-3). Other silicate minerals between 1 and 9% in the two samples included biotite, chlorite, and clays. Calcic plagioclase (anorthite / bytownite and labradorite) was also observed between 2.7 to 6.7 wt.% in one of the Argillite samples.
- Amphibole was the most abundant mineral for Basalt samples in the range of 20 to 61 wt.% (Figure 5.3-4). It is noted that diopside ($CaMgSi_2O_6$) was identified by R-XRD in some samples but may not be well resolved by QEMSCAN and could be reporting with the amphibole results in some cases. Quartz, sodic plagioclase (albite / oligoclase), and sericite / muscovite were observed at lower abundance (e.g., quartz, 5.3 to 22 wt.%; albite / oligoclase, 3.3 to 30 wt.%; sericite / muscovite, 0.17 to 6.5 wt.%. A couple of Basalt samples had calcic plagioclase (labradorite and bytownite / anorthite) identified in greater abundance than the sodic form.
- Fragmental lithologies predominantly contained quartz, plagioclase (albite / oligoclase) and sericite / muscovite (Figure 5.3-5). Biotite was observed in most samples in the range of 2.6 to 31 wt.% and a greater abundance of calcic plagioclase (anorthite / bytownite and labradorite; 1.1 to 10 wt.%), amphibole (1.4 to 5.8 wt.%), and garnet (3.2 to 3.5 wt.%) were also observed in two of the samples. Other silicate minerals included chlorite and clays in the range of 1.1 to 23 wt.%.
- More calcic plagioclase forms (e.g., anorthite / bytownite and labradorite) were detected at relatively low concentrations in most samples compared to the more sodic plagioclase forms (e.g., albite / oligoclase). A small number (eight), primarily Felsic Volcanic 1 samples had calcic plagioclase in greater abundance than the sodic form.
- Iron oxides were present in all samples at trace to moderate levels and ranged from 0.11 to 6.96 wt.%.

EMPA

EMPA was used to determine minor element concentrations in key mineral phases that were identified by QEMSCAN. The discussion below presents the minor element information by targeted mineral hosts. A summary of analyses and detailed EMPA results grouped by mineral and sample are presented in Appendix C2 including overall statistics for each mineral analyzed. Corresponding summary statistics by sample are provided in Appendix C3.

Pyrite and Pyrrhotite

- Cobalt, Ni and As occurred as minor elements in pyrite and were generally low and close to the detection limits (0.03 to 0.04 wt.%) for most samples. However, some samples contained concentrations up to 2.0, 1.1 and 1.8 wt.% Co, Ni and As, respectively. Samples identified with elevated Co, Ni and As are summarized in Table 5.3-5 along with the approach used to manage deportment calculations for the variable element contents observed.
- Similarly, Co and Ni occurred as minor elements in pyrrhotite and were also low and close to detection limits. However, more elevated Ni concentrations up to 0.7 wt.% were observed in a number of samples (Table 5.3-5). In comparison, slightly elevated concentrations of Co in pyrrhotite at up to 0.12 wt.% was observed for three Basalt samples (COL-8, HC-20, and HC-22).
- Selenium was only rarely detected in pyrite and pyrrhotite. Concentrations up to 0.28 wt.% in pyrite and 0.09 wt.% in pyrrhotite were observed in COL-33 (Fragmental 2) and COL-16 (Felsic Volcanic 1), respectively.

Arsenic Minerals

- Cobalt and Ni content in arsenopyrite varied from sample to sample. Co was consistently below the detection limit for most samples but was more elevated in some samples with concentrations up to 4.5 wt.% for COL-2 (Metasediment 2). Samples that had elevated Co usually also had elevated Ni content (but less than Co with maximum concentration 1.4 wt.%). However, sample HC-2 (Felsic Volcanic 1) with some elevated Co concentrations (up to 0.48 wt.%) consistently had Ni below detection limit, whereas sample COL-18 (Felsic Volcanic 1) contained elevated Ni at up to 0.65% but Co consistently below detection limit.
- Results confirmed sulphide and sulpharsenide mineralogy identified by QEMSCAN with one exception (COL-11 / HC-23) where two analyses of the Fe arsenide mineral loellingite ($FeAs_2$) were observed by EMPA but not detected in QEMSCAN. The loellingite composition for the two analyses completed included Co and Ni substituting for Fe. Cobalt and Ni content ranged from 2.1 to 4.7 wt.% and 4.4 to 7 wt.%, respectively.
- Gersdorffite-cobaltite analysis included fifteen points for HC-15 (Metasediment 2), a single point for COL-2 (Metasediment 2), six points for COL-7 (Basalt), and two points for COL-33 (Fragmental 2). Though the number of analyses were limited, the results indicate variability in Co and Ni content with Co-rich (cobaltite) identified in three of the samples (COL-2, COL-7, COL-33) and Ni-rich (gersdorffite) identified in the fourth (HC-15). Solid solution Fe content for cobaltite analyses ranged from 4.9 to 8.6 wt.% and for gersdorffite 9.0 to 11 wt.%.
- Analyses of gersdorffite in HC-15 (Metasediment 2) detected Sb at up to 0.17 wt.%, while cobaltite analyzed in COL-2 (Metasediment 3) and COL-7 (Basalt) had undetectable Sb.
- Antimony concentrations in arsenopyrite were generally at or below detection limit with a few analyses above detection and one analysis out of 77 with an Sb content of 0.6 wt.%.
- Selenium was not detected in arsenopyrite or gersdorffite-cobaltite although detection limits were elevated (0.26 wt.%) in comparison to other minerals (0.02 to 0.03 wt.%).

Sphalerite

- Iron solid solution replacing Zn in sphalerite generally varied over a narrow range within a given sample but was as low as 0.4 wt.% for COL-27 (Felsic Volcanic 2), a sample with a small amount of sphalerite. Median Fe concentrations in sphalerite for the rest of the samples analyzed ranged from 2.5 to 7.5 wt.%. Cadmium and Mn were consistently detected as minor elements in sphalerite with Cd present at up to 0.6 wt.% and Mn up to 0.4 wt.%. Selenium was consistently less than 0.03 wt.%.

Chalcopyrite

- Minor elements substitutions in chalcopyrite were low with Co, Ni and Se consistently less than 0.03 wt.%.

Galena

- For the three samples analyzed, minor elements substitutions in galena were not detected with the exception of selenium around the detection limit (0.03 wt.%). The highest selenium concentration (up to 0.6 wt.%) was observed for HC-4 (Felsic Volcanic 1).

5.3.7 RESULTS – MINERAL / ELEMENT ASSOCIATIONS AND DEPORTMENT

Based on the mineralogical analysis completed some elements are singly associated with specific minerals. Cadmium and Zn were hosted only by sphalerite, molybdenite was the only host for Mo, and galena was the only mineral host for Pb. Copper was primarily hosted by chalcopyrite with very low concentrations of Cu sometimes observed in pyrite and pyrrhotite. Selenium and Sb were observed in minor to trace concentrations and exhibited limited resolution in the current work. Consistent with low to undetectable solid phase concentrations in the samples, Hg was not observed in QEMSCAN or EMPA analyses.

For other elements including As, Co, Fe and Ni, element associations among the sulphide minerals is more complex and described herein as deportment. Element and mineral associations for the deportment analysis that follows is summarized in Table 5.3-6.

Iron Deportment

As discussed previously, the sulphide Fe fraction is not an element of direct environmental interest but rather is potentially important in minor element mobility due to interactions during sulphide oxidation. Iron oxyhydroxides formed by sulphide oxidation also have the potential to adsorb dissolved As and metals.

The proportion of Fe hosting sulphide mineral phases are shown in Figure 5.3-6. Note that the sample order for this plot is grouped first by lithology and then by increasing ABA total S content.

- The Felsic Volcanic 1 samples had most Fe from pyrite. Three samples (COL-19, COL-21, HC-34) had a greater proportion of Fe from pyrrhotite than pyrite and two samples (COL-16 and HC-2) had the main Fe hosts split among pyrite, arsenopyrite and pyrrhotite. Greater than 10% of the Fe was hosted in chalcopyrite in two samples (HC-6 and COL-22). Four samples (COL-30, COL-22, HC-4, and HC-9) had greater than 5% of the Fe in sphalerite.
- The Felsic Volcanic 2 samples, similar to Felsic Volcanic 1 samples, had Fe primarily from pyrite or a mix of pyrite and pyrrhotite. Two of the samples (COL-17 and COL-26) had arsenopyrite and pyrite as the main Fe hosts.
- Metasediment samples (MS2 and MS3) had Fe primarily hosted in both pyrite and pyrrhotite.
- Basalt samples also had mixed Fe from both pyrite and pyrrhotite with a generally higher proportion from pyrrhotite. About half of the Basalt samples had greater than 5% of the Fe from chalcopyrite.
- Fragmental 2 samples had Fe primarily hosted in pyrrhotite for three samples (COL-31, COL-34, HC-35), arsenopyrite for one sample (COL-32), and mixed pyrite and pyrrhotite for one sample (COL-33). The Fragmental 1 sample had Fe almost completely from pyrite while the two argillite samples had Fe exclusively from pyrite and pyrrhotite.

Arsenic Deportment

The proportion of As hosting sulphide mineral phases are shown in Figure 5.3-8 grouped by lithology. Note that for this plot the arrangement of samples within each lithology is by increasing As content.

- Pyrite or arsenopyrite were the primary As hosts in most samples for all lithologies with some Felsic Volcanic 1 and Felsic Volcanic 2 samples having a mixture of pyrite and arsenopyrite.
- Pyrite or arsenopyrite were the primary As host in most Metasediment and Fragmental samples. Some samples had gersdorffite-cobaltite as the primary As host including Metasediment 2 (HC-15), Metasediment 3 (COL-5, COL-6), and Fragmental 2 (HC-36, COL-33). The single Metasediment 2 sample (HC-15) with the more Ni-rich form (gersdorffite) identified had relatively high S and As content. All other samples with this As host mineralogy typically had the more Co-rich form (cobaltite) and low S (≤0.2%) content.
- Pyrite or arsenopyrite were the primary As host in most Basalt samples. Some samples of basalt (HC-22, COL-7, COL-8) had gersdorffite-cobaltite as the main As host. The Co rich (cobaltite) end member was identified in one Basalt sample (COL-7).

Cobalt and Nickel Deportment

Sulphide mineral proportions that host Co and Ni are shown in Figure 5.3-9 and Figure 5.3-10 respectively. Note that for these plots the arrangement of samples within each lithology is by increasing Co and Ni content.

- Pyrite was the primary Co host for most samples, followed by gersdorffite-cobaltite in some Metasediment (COL-2; Metasediment 2, HC-15; Metasediment 2, COL-5; Metasediment 3, COL-6; Metasediment 3), Basalt (COL-7, COL-8, HC-22), and Fragmental 2 (COL-33 and HC-35) samples and arsenopyrite in one Felsic Volcanic 1 sample (HC-34), one Basalt sample (HC-23 / COL-11), and two Fragmental 2 (COL-31 and COL-32) samples. One Felsic Volcanic 1 sample (HC-2) and two Felsic Volcanic 2 samples (COL-17 and COL-26) had a mixture of Co from pyrite and arsenopyrite.
- Pyrite was the primary Ni host in Felsic Volcanic samples. Felsic Volcanic 1 samples often had pentlandite as a prominent Ni host including three samples where it was the primary host (HC-7, HC-29, COL-29). Other samples had pyrrhotite as an important host (HC-2, COL-19, and COL-

29) and in one case was the primary Ni host (HC-34). Pyrrhotite and arsenopyrite were other prominent hosts of Ni in most Felsic Volcanic 2 samples.

- Mixtures of varying Ni host minerals including pyrite, pyrrhotite, gersdorffite-cobaltite, and pentlandite were common in Metasediment and Basalt samples. Pyrite was the primary Ni host in one Metasediment 2 sample (COL-4) and gersdorffite-cobaltite was the primary Ni host in one Basalt sample (COL-7).
- The two Argillite samples had Ni primarily from pyrite and pyrrhotite with one sample also identifying pentlandite.
- The Fragmental 1 sample had Ni primarily from pyrite with a small amount from pentlandite. The Fragmental 2 samples had Ni primarily in the form of mixtures of varying Ni host minerals including pyrrhotite, arsenopyrite, gersdorffite-cobaltite, and pentlandite.

5.3.8 RESULTS – COMPARISON WITH STATIC RESULTS

QEMSCAN and Geochemical Data Comparison

QEMSCAN totals were reconciled by SGS Lakefield to the chemical analysis for TC, total S and major cations by digestion-ICP analysis. Results were in generally good agreement (SGS reports in Appendix C1).

Reconciliation of the minor elements of interest for this study are provided in Appendix C4. Comparisons included: mineralogy program subsample (ICP-OES or ICP-MS) and static testing results (ICP-MS); mineralogy program subsample (ICP-OES or ICP-MS) and QEMSCAN / deportment totals; and QEMSCAN / deportment and static testing results (ICP-MS). Comparison of Se and Sb were not included since they were present at low concentrations with poor resolution in the quantitative mineralogy analysis. Due to low sphalerite content in the samples for the second stage of analysis, Cd content was also notably low and deportment was not quantified or compared for those samples.

- Four acid ICP-OES or ICP-MS for the mineralogy subsample when compared to the static program four acid ICP-MS analysis had generally good agreement for all elements including As, Cd, Co, Cu, Pb, Mo, Ni and Zn though some original static testing results were limited by more elevated ICP-OES detection limits. Results suggest good replication during the subsampling process.
- Four acid ICP-OES or ICP-MS for the mineralogy subsample when compared to the deportment totals were similarly in generally good agreement for As, Cd, Cu, Pb and Zn subject the ICP-OES analytical detection limits for the original sample set. Cobalt, Mo and Ni showed more scatter with a less distinct trend. The lack of a trend for Mo is attributed to low Mo concentrations in the samples. However, in the case of Co and Ni, poor fits in results probably indicate poor resolution in the QEMSCAN deportment calculations and assumptions since those elements are also distributed among multiple hosting minerals with variable stoichiometry (e.g., Co and Ni in gersdorffite-cobaltite, Co and Ni in arsenopyrite, Co and Ni in pyrite and Ni in pentlandite and pyrrhotite).
- Comparison of static results (ICP-MS) and QEMSCAN deportment results also have generally good agreement for As, Cd, Cu, Pb, and Zn with increasing scatter at decreasing concentrations. As for the mineralogy subsample and QEMSCAN results above, reproducibility for Co, Mo and Ni is generally poor and probably reflects low concentrations for Mo and poor resolution in deportment calculations for Ni and Co.

It was noted that the deportment calculated As sometimes underestimated the measured As content in the sample. This may represent poor detection of a high As content phase in relatively low abundance for those samples. Therefore, an estimate of the possible missing As sulphide was calculated for these samples when deportment calculated As totaled less than 90% of the measured As.

- An As concentration was assigned to an inferred As sulphide by subtracting the QEMSCAN As from the As determined by static testing. The As deportment was then recalculated for each host mineral phase based on the total As from static testing.

- For samples inferred to be missing a possible As sulphide in the QEMSCAN analysis, a check was made that the small amount of additional S was still in general agreement with the total ABA S value. For these samples the results agreed within the limits of expected analytical variation.
- Based on these calculations, corrected As deportment data was produced and is shown in Figure 5.3-11, which now includes an undifferentiated (und.) As sulphide phase. Arsenic sulphide (und.) likely represents unquantified arsenopyrite or in some cases gersdorffite-cobaltite. Note that the arrangement of samples within each lithology is by increasing As content in Figure 5.3-11.

As noted previously, Fe associated with sulphide in the samples may be of particular importance for metal leaching. Total Fe derived by four acid digest for most samples will overestimate Fe in sulphide phases as Fe from crystalline Fe oxides and Fe in silicate minerals are likely to be released during four acid digestion. Aqua-regia digest is potentially more suitable since it is expected to dissolve sulphide minerals, with little or more limited dissolution of Fe from the crystalline oxide and silicate fractions.

- A comparison of QEMSCAN sulphide Fe with aqua-regia and four acid extracted Fe from static data for the mineralogy sample set is provided in Figure 5.3-12. Results identified slightly higher but somewhat similar Fe extraction for most lithologies in the four acid digest compared to the aqua-regia digest.
- Only the Basalt samples with more mafic minerals had substantially more Fe extracted by the four acid digest.
- Results also indicated aqua-regia Fe is only a good predictor of sulphide Fe at high sulphide content. For lower sulphide content samples small quantities of non-sulphide Fe in the aqua-regia digest become a substantial fraction of the Fe observed making the association poor.

Comparison of Detailed (QEMSCAN) and Static (R-XRD) Mineralogy

The R-XRD and available QEMSCAN data for samples where there are results from both methods (n=43) were compared in Appendix C5. The results were similar overall for major minerals identified (generally greater than 10%). As expected QEMSCAN was able to identify minor and trace minerals in the samples. Though the QEMSCAN method was able to resolve lower concentration minerals in the samples based on chemical signatures of individual particles, R-XRD is complimentary since the analysis is based on the X-ray diffraction response to mineral structures.

The focus of this work was on characterizing the carbonate and sulphide mineral fractions in the samples. Generally, other major and minor silicate and oxide minerals were also classified by QEMSCAN, but there are a few notable considerations due to the differences in analytical techniques which are identified below:

- Clay minerals by QEMSCAN will not align directly with R-XRD results. QEMSCAN will group a number of clay minerals (e.g., kaolinite, illite, montmorillonite) due to limited chemical spectra by grain size. For the Project data, R-XRD identified kaolinite in a few samples and grouped illite with sericite / muscovite. In addition, fine grained mica minerals (muscovite and biotite) and chlorite may also be grouped with clays in the absence of good chemical spectra.
- Diopside ($CaMgSi_2O_6$) was identified by R-XRD in about half the samples without a corresponding phase by QEMSCAN. Diopside may be grouped with amphiboles by QEMSCAN since various calcium silicates can be difficult to resolve with QEMSCAN alone.
- Dravite ($NaMg_3Al_6(BO_3)_3Si_6O_{18}(OH)_4$) was identified in two samples by R-XRD including one sample at 10 wt.% but was not identified by QEMSCAN. QEMSCAN cannot detect B (low atomic mass) and the composition of dravite is otherwise very similar to chlorite so QEMSCAN may be classifying dravite as chlorite when present.
- Trace concentrations of rutile were reported by R-XRD but not identified by QEMSCAN.

Mineralogy Analysis of AP

ABA data and corresponding speciated sulphide results from detailed mineralogy are tabulated for reference in Appendix C6. QEMSCAN results identified acid generating sulphide minerals (pyrite, pyrrhotite, chalcopyrite, arsenopyrite, gersdorffite-cobaltite, pentlandite and molybdenite) and non-acid generating sulphides (sphalerite and galena).

Sulphate S (assumed to be present as gypsum / anhydrite) was detected in low abundance in all samples in QEMSCAN which contrasted distinctly with sulphate determinations by ABA at notably higher concentrations. The difference appears to be as a result of overestimated sulphate in ABA by dissolution of pyrrhotite in some samples as hypothesized in Section 5.2.4.

- QEMSCAN sulphate S was observed with a range of 0.001 to 0.028% and ABA sulphate S ranged from 0.01 to 6%. As discussed in Section 5.2, higher ABA sulphate S (by the HCl leach test) was inferred to be related to pyrrhotite dissolution, which is a known interference in the test.
- A plot of QEMSCAN sulphate and pyrrhotite S vs. ABA sulphate S (Figure 5.3-13) supports the pyrrhotite dissolution hypothesis with increasing sulphate S observed with increasing pyrrhotite S content.
- Two moderate to high S Felsic Volcanic 1 samples (e.g., COL-14 and COL-18) identified notably higher ABA sulphate S than pyrrhotite S. Pyrite is the primary sulphide phase in these samples by QEMSCAN and assuming all of the pyrite was resistant to dissolution in the HCl extraction, the higher sulphate S concentrations for these samples may indicate an underestimate of pyrrhotite content by QEMSCAN in these pyrite rich samples or subsample variability.

To further support an understanding of AP in the samples, the distribution (deportment) of S among the various sulphide minerals is provided in Figure 5.3-14. Samples are grouped by lithology and arranged by increasing ABA total S content.

- All samples among the lithologies had S mostly associated with acid generating sulphide minerals, which most often included pyrite or a combination of pyrite and pyrrhotite.
- Other acid generating sulphide minerals included chalcopyrite and arsenopyrite. Chalcopyrite made up more than 5% of the sulphide fraction in three Felsic Volcanic 1 samples and over half of the Basalt samples. Arsenopyrite was more than 10% of the sulphide fraction for two Felsic Volcanic 1, two Felsic Volcanic 2, and two Fragmental 2 samples.
- Non-acid generating sulphides identified included sphalerite and galena. Sphalerite was more than 10% of the sulphide fraction in six of the Felsic Volcanic 1 samples. It is noted that the Fe content of sphalerite may result in potential for acid generation from the Fe fraction of sphalerite, but the amount is small and has not been considered for the purpose of this analysis. Galena, where detected, was most prominent in Felsic Volcanic 1 samples and up to 1.5% in one sample.
- Though sphalerite content was generally low in mine rock, high proportions tended to be noted in higher sulphide (>2.5% S) Felsic Volcanic 1 samples (as noted in Section 5.2.4). A greater proportion of chalcopyrite also tended to be observed in lower sulphide content Basalt samples (<0.5% S). Otherwise, no particular relationships were noted in sulphide assemblages with overall variations in sulphide content.

The analysis included comparisons of ABA MPA and AP to comparable calculated values from the speciated S results by QEMSCAN.

- As discussed previously, for this Project due to the presence of pyrrhotite, total S and MPA is expected to be the most appropriate measure of acid potential.
- QEMSCAN MPA and ABA MPA results were in generally good agreement (Figure 5.3-15) reflecting good overall reproducibility between the two methods. Considering the available S speciation of QEMSCAN, the ABA MPA and QEMSCAN AP calculated using only the acid generating sulphides were compared. Results were only marginally different reflecting small changes in only the subset of Felsic Volcanic 1 samples with elevated concentrations of sphalerite.
- Similar plots comparing QEMSCAN AP and ABA AP (Figure 5.3-16) based on sulphide S had similar trends, but greater scatter due to loss of pyrrhotite in the ABA HCl leach discussed previously.

Mineralogy Analysis of NP

ABA data and corresponding speciated carbonate results from detailed mineralogy are tabulated for reference in Appendix C6. QEMSCAN results identified calcite, dolomite and ankerite, which were used to calculate QEMSCAN CarbNP for comparison to ABA CarbNP data (Figure 5.3-17).

- Generally good agreement was observed between the two methods on the basis of total carbonate mineral content. For some samples QEMSCAN appeared to underestimate the CarbNP. Alternatively, the ABA CarbNP near the TIC detection limit may be overestimated.
- Comparison of the NP determination by titration and the non-Fe-bearing $CaCO_3$ equivalent content from calcite and dolomite ($CarbNP_{Cal+Dol}$) is also provided [5]. At NP above approximately 18 kg $CaCO_3$/t results for NP and $CarbNP_{Cal+Dol}$ were similar. The NP was generally higher than $CarbNP_{Cal+Dol}$ for lower NP results indicating the presence of non-carbonate NP measured in the titration. It was also noted that the Metasediment 2 samples with low $CarbNP_{Cal+Dol}$ had the most notably elevated NP by titration. This may be due to the higher content of biotite and chlorite noted in these samples.
- Overall, the results confirm that only a small fraction (17 to 33%) of the NP is present as Ca carbonate in most samples with a Modified NP <18 kg $CaCO_3$/t.

CarbNP speciation grouped by lithology and arranged by increasing ABA CarbNP content is provided in Figure 5.3-18. The mineralogical interpretation of NP in the samples is described below.

- The carbonate NP from QEMSCAN calcite and dolomite for the sample set ranges from 0.2 to 110 kg $CaCO_3$/t for all samples and 0.2 to 65 kg $CaCO_3$/t for samples excluding Basalt, indicating that Basalt has generally higher CarbNP than other lithologies.
- No low CarbNP samples common in most lithologies were present among the Basalt samples (QEMSCAN CarbNP range 22 to 110 kg $CaCO_3$/t).
- Calcite is the predominant carbonate mineral among the samples. COL-25 (Felsic Volcanic 2) and HC-33 (Felsic Volcanic 1) had notably elevated proportion of ankerite (28 to 39%), and COL-3 (Metasediment 2) had almost 80% of carbonate as dolomite. Dolomite is present in some samples but when present represents 20% or less of the CarbNP.
- Only small quantities of ankerite (that may provide no net neutralization) were detected. A single sample of Felsic Volcanic 1 and Felsic Volcanic 2 had ankerite at almost 40% and 30%, respectively, of measured CarbNP. Metasediment 2 samples had more than half of the samples with ankerite detected, but at a few percent or less of the CarbNP. Except for the higher ankerite samples already mentioned, ankerite representing 5% or more of the CarbNP was only observed in two Felsic Volcanic 1 samples and one Basalt sample.
- Calcium carbonates are expected to be the only effective neutralizing minerals for most mine rock. However, QEMSCAN showed some potentially reactive non-CarbNP in some samples that may be effective for the lower S content samples with low sulphide oxidation rates.

Silicate minerals that may have potential to provide some limited neutralization capacity at very low sulphide content and corresponding low sulphide oxidation rates are present but overall at relatively low proportions in the samples tested. General observations are identified here for information purposes.

- Minerals expected to have low reactivity and provide essentially no NP include quartz, sodic plagioclase (albite / oligoclase) and sericite / muscovite. These minerals represent the bulk of the silicate fraction at about 50 to 90% by mass for all samples except Basalt and around 10 to 50% for Basalt samples.
- Basalt has about 40 to 50% of the silicate mass as amphibole or amphibole and garnet which may have some limited neutralization capacity at low rates of sulphide oxidation.
- Biotite and chlorite have been noted to be present in consistently higher amounts in Metasediment 2 and Fragmental 2 samples (up to 30 to 40% by mass combined) which similarly may provide some limited neutralization capacity at low rates of sulphide oxidation.
- Other minerals with some potential to neutralize low rates of acidity include calcic plagioclase (labradorite and anorthite / bytownite) and the aforementioned biotite and chlorite which are present in variable amounts among all of the samples.

[5] Though ankerite was low in these samples, it was excluded from the comparison considering its lower reactivity and potential for no net neutralization from the iron fraction of the mineral.

The above observations on potential non-carbonate NP in samples studied is supported by response of low NP samples (e.g., <20 kg $CaCO_3$/t) in the Modified NP test.

- These low NP samples tend to exhibit increasing proportions of non-CarbNP in comparison to the measured CarbNP.
- Metasediment 2 samples in particular appear to have the highest measured non-CarbNP in comparison to CarbNP and it is noted these samples also contain more elevated biotite and chlorite content.
- The relevance of the apparent small amount of non-carbonate NP in some samples needs to be assessed in the context of corresponding low sulphide content rock. Humidity cell testing underway includes low sulphide content and low NP samples for this purpose.

5.3.9 KEY FINDINGS

Detailed mineralogy has confirmed variable sulphide mineral content with most samples containing pyrite and some containing a mixture of pyrite and pyrrhotite. Samples contained variable quantities of other sulphide and sulpharsenide minerals including sphalerite, arsenopyrite, gersdorffite-cobaltite, galena, chalcopyrite and pentlandite. Trace amounts of molybdenite were identified in some samples. Minor element concentrations of the various sulphides have also been determined across the range of samples tested.

The work also identified calcite as the primary carbonate mineral and identified other potentially neutralizing minerals to support interpretation of NP and humidity cell testing for the project.

Sulphides, Metal Deportment and AP

Key findings related to AP and sulphide mineralogy are summarized below.

- QEMSCAN analysis identified the presence of only trace quantities of sulphate (assumed to be gypsum) and confirmed that dissolution of pyrrhotite in the ABA HCl sulphate was responsible for the more elevated sulphate reported for the ABA analyses.
- Pyrite or pyrite and pyrrhotite are the primary sulphide minerals present in most samples.
  - In addition to potentially different sulphide oxidation processes and rates for pyrrhotite vs. pyrite among the samples, the sulphide Fe fraction is potentially important in limiting mobility of As and other elements as it oxidizes and forms secondary Fe oxyhydroxides and other Fe phases in the initial stages of sulphide oxidation.
  - Sulphide Fe for Felsic Volcanic 1 samples is primarily from pyrite and for Felsic Volcanic 2 samples is sometimes more from pyrite and sometimes more from pyrrhotite.
  - The pyrrhotite Fe fraction tends to predominate for other lithologies including metasediments, Fragmental 2, Basalt and Argillite.
  - A substantial portion (>20%) of the sulphide Fe can also be due to other (non-pyrite) Fe-bearing sulphides including arsenopyrite and chalcopyrite when present in high abundance, especially for Felsic Volcanic 1, Felsic Volcanic 2 and Fragmental 2 lithologies.
- Arsenic hosting mineralogy includes low As pyrite, higher As pyrite, arsenopyrite and gersdorffite-cobaltite that varies among the samples and lithologies tested.
  - Arsenic in Felsic Volcanic rocks was primarily hosted by varying quantities of arsenopyrite and generally low As concentrations in pyrite.
  - Pyrite and / or arsenopyrite were the primary As host in most Basalt, Metasediment, and Fragmental samples.
  - The As-bearing sulphide gersdorffite-cobaltite was observed to be the primary As host mineral in some samples of Basalt, Metasediment 2, Metasediment 3 and Fragmental 2 lithologies. It was essentially absent from Felsic Volcanic samples.
  - Argillite had As in pyrite.
- Cobalt hosting mineralogy included gersdorffite-cobaltite and variable Co substitution in pyrite and arsenopyrite. The primary Co host mineralogy varied among samples and different lithologies.

  - Felsic volcanic samples had Co primarily hosted in pyrite and sometimes arsenopyrite.
  - For Metasediments, Fragmental 2 and Basalt samples, the primary Co host varied among pyrite, arsenopyrite and gersdorffite-cobaltite.
  - Argillite had Co in pyrite.
- Nickel hosting mineralogy included a number of sulphide minerals including pentlandite, gersdorffite-cobaltite, and variable Ni substitution in pyrite, arsenopyrite, and pyrrhotite. The Ni host mineralogy varied among samples and different lithologies.
  - Nickel in Felsic Volcanic samples was primarily in pyrite and sometimes in pyrite and pyrrhotite.
  - Some Felsic Volcanic 1 samples had Ni primarily in pentlandite and a few samples of Felsic Volcanic 1 and Felsic Volcanic 2 had 10 to 30% of the Ni in arsenopyrite.
  - Nickel distribution in Metasediments and Basalt was also sometimes in pyrite and pyrrhotite but generally was distributed among three or more sulphides including pyrite, pyrrhotite, pentlandite and / or gersdorffite-cobaltite.
  - Fragmental 2 samples were more variable with major Ni hosts that included gersdorffite-cobaltite, arsenopyrite, pyrrhotite and pentlandite that varied from sample to sample.
  - Argillite had Ni in pyrite and pyrrhotite or pyrite, pyrrhotite and pentlandite.
- Zinc and Cd were hosted in sphalerite that had a variable Fe content up to 7.5 wt.% and minor Mn up to 0.4 wt.%.
  - Sphalerite, though generally low among the samples, was identified as a generally high proportion of the sulphide fraction of Felsic Volcanic 1 samples that contained >2.5% sulphur.
  - Since sphalerite is non-acid generating at neutral pH, the high sphalerite content of high sulphide Felsic Volcanic 1 humidity cells should be factored into the interpretation of the observed leaching behaviour of these humidity cells.
- Lead was hosted in galena that was present in some samples and was not identified as a neutral metal leaching concern in column tests. The only minor element noted in galena was Se at up to 0.6 wt.% in one of three samples and at or below detection in the other two samples.
- Copper was hosted primarily in chalcopyrite. The low sulphide Basalt samples (<0.5% S) appeared to have a greater proportion of chalcopyrite.
- Antimony and Se were present at very low to undetectable concentrations among the sulphide minerals and were not well resolved in this study.
  - Antimony concentrations in arsenopyrite were rarely detected. Analyses of gersdorffite in HC-15 (Metasediment 2) detected Sb at up to 0.17 wt.%, while cobaltite analyzed in COL-2 (Metasediment 3) and COL-7 (Basalt) had undetectable Sb.
  - Selenium was only rarely detected in pyrite, pyrrhotite and galena.
  - Selenium was not detected in chalcopyrite, sphalerite, arsenopyrite or gersdorffite-cobaltite, although more elevated detection limits were observed for As minerals due to matrix effects.

Mineralogy and NP

Key findings related to mineralogy and NP are summarized below.

- Calcite is the predominant carbonate mineral among the samples. COL-25 (Felsic Volcanic 2) and HC-33 (Felsic Volcanic 1) had notably elevated proportion of ankerite (28 to 39%), and COL-3 (Metasediment 2) had almost 80% of carbonate as dolomite. Dolomite is present in some samples but when present represents 20% or less of the CarbNP.
- No low CarbNP samples (<20 kg $CaCO_3$/t) common in most lithologies were present among the Basalt samples.
- Only small quantities of ankerite (that may provide no net neutralization) were detected. However, a sample of Felsic Volcanic 1 and a sample of Felsic Volcanic 2 had ankerite at almost 40% and 30%, respectively, of the measured CarbNP.

- Ankerite was detected in more than half of the Metasediment 2 samples, but only composed a few percent or less of the CarbNP.

The focus of the QEMSCAN work was on identifying and characterizing sulphide and carbonate minerals. Ca carbonate minerals were expected to be the only effective neutralizing minerals for most mine rock. However, QEMSCAN confirmed some potentially reactive non-carbonate mineral NP in some samples (especially Basalt) that may be available and effective for low S content samples and low sulphide oxidation rates.

- Minerals expected to have low reactivity and provide essentially no NP include quartz, sodic plagioclase (albite / oligoclase) and sericite / muscovite. These minerals represented the bulk of the silicate fraction at about 50 to 90% by mass for all samples except Basalt where they represented between 10 to 50% of the sample mass.
- The results confirm that for the low NP (non-Basalt) samples with a Modified NP <18 kg $CaCO_3$/t only a small fraction (17 to 33%) of the NP is present as Ca carbonate.
- Basalt has about 40 to 50% of the silicate mass as amphibole or amphibole and garnet which may have some limited neutralization capacity at low rates of sulphide oxidation.
- Biotite and chlorite have been noted to be present in consistently higher amounts in Metasediment 2 and Fragmental 2 samples (up to 30 to 40% by mass combined) which similarly may provide some limited neutralization capacity at low rates of sulphide oxidation.
- Other minerals with some potential to neutralize low rates of acidity include calcic plagioclase (labradorite and anorthite / bytownite) and the aforementioned biotite and chlorite which are present in variable amounts among all of the samples.
- The relevance of the apparent small amount of non-carbonate NP in some samples needs to be assessed in the context of corresponding low sulphide content rock. Humidity cell testing underway includes low sulphide content and low NP samples for this purpose. Should non-carbonate mineral NP be identified as a potential benefit, more detailed analysis of silicate minerals may be appropriate.

Table 5.3-1: Detailed Mineralogy Samples

Rock Type	Rock Type ID	Related Column Tests	Related Humidity Cells	Number of Detailed Mineralogy Samples
Felsic Volcanic 1	FV1	13	16	28
Felsic Volcanic 2	FV2	5	4	9
Metasediment 2	MS2	3	3	6
Metasediment 3	MS3	2	3	5
Fragmental 1	Frag1	-	1	1
Fragmental 2	Frag2	4	1	5
Basalt	Basalt	6	6	9
Argillite	S1A	1	1	2
Total [(1)]		34	35	65

Notes:

1 *Total number of detailed mineralogy samples is equal to 65 due to the same sample (e.g., FV1: DX450232 and Basalt: DX450022, DX450113, DX550101) used for both column and humidity cell testing.*

Notes:

1 Element content by four acid leach.

2 Total sulphur by ABA.

3 Modified Sobek neutralization potential.

4 Statistical descriptions are relative to the specific lithology in the ML / ARD database based on aqua regia for all cells and columns except for the argillite samples HC-26 and COL-1. If not specified directly, 'elevated' refers to greater than the 75th percentile rank, 'typical' refers to between the 40th and 75th percentile rank, and 'low' refers to lower than the 40th percentile rank among the dataset for the lithology. Further details provided for specific elements in the table.

Table 5.3-3: Summary of EMPA Sulphide and Sulpharsenide Mineral Analysis

Mineral	Mineral Formula	Quantified Minor Elements	# of Analyses
Pyrite	FeS_2	Co, Ni, Cu, As, Se	603
Pyrrhotite	$Fe_{1-x}S$	Co, Ni, Cu, Se	431
Sphalerite	(Fe,Zn)S	Cd, Mn, Cu, Se	122
Arsenopyrite	FeAsS	Co, Ni, Sb, Se	77
Chalcopyrite	$CuFeS_2$	Co, Ni, Se	24
Galena	PbS	Se	31
Gersdorffite-Cobaltite	(Fe,Ni,Co)AsS	Sb, Se	24

Table 5.3-4: General Approach for EMPA Analysis

QEMSCAN Mineral Abundance (%)	# of Analysis
>1%	15
0.2 to 1	10
0.1 to 0.2	5
<0.1	*

Notes:

* *For low sulphide content samples 2 to 5 target attempts were included for pyrite, pyrrhotite, sphalerite, chalcopyrite, galena, arsenopyrite and gersdorffite-cobaltite. The overall priority was directed to analysis of pyrite, pyrrhotite, arsenopyrite, gersdorffite-cobaltite and sphalerite within the allocated effort for the work.*

Table 5.3-5: EMPA Applied Concentration for Ni, As and Co Deportment

n=53 samples, HC-1 to HC-27, COL-1 to COL-30			
Mineral	EMPA *	% Ni Applied	Applicable Samples
Pyrite	Ni >0.1%	0.18	HC-3 (FV1), COL15 / HC-5 (FV1), COL-20 (FV1), COL-29 (FV1), COL-17 (FV2), HC-14 (MS2), COL-2 (MS2), HC-20 (Basalt), COL-8 (Basalt)
	Average Ni <0.1%	0.07	All other samples

5.4 HUMIDITY CELL TESTING

5.4.1 OVERVIEW

Testing consisted of 35 humidity cells prepared with drill core samples. The test samples were selected to be representative of key Project rock types as shown in Table 5.4-1. The humidity cell test samples represent the range of geochemical characteristics observed in the static tests for both mine rock and ore-grade materials.

Humidity cell testing described in this report was initiated in stages, including 27 tests (HC-1 to HC-27) initiated in May 2023 and eight tests (HC-28 to HC-35) initiated in April 2024.

This section presents data for cells HC-1 to HC-35 that was collected up to July 2025. Currently available data includes:

- 109 weeks of data for the humidity cells initiated in May 2023.
- 63 weeks of data for the humidity cells initiated in April 2024.

The tests continue to be monitored as appropriate.

The approach and testing methods utilized herein are based on the requirements described under the *Ontario Mining Act*; namely guidance found within the reference document *Prediction for Drainage Chemistry for Sulphidic Geologic Materials* (MEND 2009), which represents best practice and industry-standard approaches and methodologies for ML / ARD sampling and characterization in Canada.

5.4.2 TESTING DETAILS

A summary of humidity cell testing is provided below. Geochemical descriptions of the test samples are summarized in Table 5.4-2. Mineralogical data from R-XRD and QEMSCAN for the humidity cell samples is provided in Table 5.4-3.

Samples were selected following completion of static testing on drill core samples (Section 5.2) to represent key rock types in the mine volume, including the LP Central pit, Viggo pit and underground mine, based on current mine design. Samples include a range of sulphide, NP and metal content of both mine rock and ore-grade material from the following lithologies: Felsic Volcanic (FV1, FV2), Metasediment (MS2, MS3), Fragmental (Frag1, Frag2), Basalt and minor Argillite. Static test results indicated that both mine rock and ore-grade samples typically encompassed similar ranges of S, NP and solid phase metal contents. Therefore, the samples selected for humidity cell testing were chosen to represent the broad range of geochemical characteristics observed for mine rock and ore-grade materials.

All tests are conducted at the SGS laboratory in Lakefield, Ontario, following the procedures described in MEND (2009) and detailed in Appendix A.

The humidity cells are operated as standard mine rock humidity cell tests. The tests were prepared with 0.5 to 1 kg of prepared drill core and flushed weekly with 0.5 to 1 L of deionized water (i.e., a 1:1 water to rock ratio was maintained). Leachates were analyzed weekly for the parameters listed in Section 4.4.1.

- HC-1 to HC-27 were initiated in May 2023.
  - In April 2024 the analytical schedule was updated to analyze dissolved metals on a biweekly basis for HC-1 to HC-27, and to discontinue chloride and fluoride analyses [6] for all cells except for HC-15, HC-19 and HC-26. Chloride analysis for HC-15 and HC-26 and fluoride analysis for HC-19 were modified to a biweekly schedule in April 2024. Chloride analysis for HC-19 and fluoride analysis for HC-15 were discontinued in April 2024. Fluoride analysis for

[6] Chloride and fluoride analyses were discontinued when concentrations were consistently below the analytical detection limit.

HC-19 was discontinued in July 2024. Chloride analysis for HC-15 and HC-26 was discontinued in May 2025.

  - In May 2025 the analytical schedule was updated to analyze dissolved metals on a monthly basis for cells HC-8 to HC-27.

- HC-28 to HC-35 were initiated in April 2024.
  - In May 2025 the analytical schedule was updated to analyze dissolved metals on a biweekly basis for cells HC-28 to HC-35 and discontinue chloride and fluoride analysis in those cells.

Changes were made to the analytical detection limit for several analytes throughout the testing as follows:

- The detection limit for sulphate was modified from 2 to 0.2 mg/L in June 2024, following a change in the sulphate analytical method from colorimetry to ion chromatography. This change was made under the direction of WSP and Great Bear Resources, to support obtaining measurable sulphate concentrations for all the tests.
- The detection limit for chloride was reduced from 1 to 0.2 mg/L in June 2024, alongside sulphate, as part of a change in the analytical method from colorimetry to ion chromatography.
- Following routine annual instrument review by the laboratory, detection limits were modified for several elements including S (from 3 to 5 mg/L), Cu (from 0.0002 to 0.002 mg/L), Mo (from 0.00004 to 0.0004 mg/L), and W (from 0.00002 to 0.0002) in January 2024. The detection limit for Cu was further modified from 0.002 to 0.001 mg/L in February 2024.
- In May 2025, ultra-trace analysis of Hg was incorporated into the analytical schedule for all humidity cell tests to detect Hg at the sub-nanogram level (0.00000004 mg/L). Ultra-trace Hg analyses [7] are conducted at Flett Research Ltd. In Winnipeg, Manitoba through a method based on Cold Vapor Atomic Fluorescence Spectroscopy (CVAFS).

Leachate chemistry was used to calculate release rates based on estimated surface areas of the humidity cell samples. Calculated release rates (expressed as mg/m^2/week) were used to determine trends in metal release, the rates of sulphide oxidation and NP depletion, and to estimate the lag time to acid onset in the samples.

5.4.3 QUALITY ASSURANCE AND QUALITY CONTROL

Humidity cell leachate data were reviewed for QA / QC purposes through continuous review. QA / QC evaluation included:

- Assessment of laboratory QA / QC reports, including method blanks, laboratory duplicates, and spike recoveries.
- Verification of detection limits.
- Review of ionic charge balance.
- Review of anomalous data spikes.
- Comparison of results from total S (by ICP-MS) versus sulphate S (by IC) measured in the leachate.
- Comparison of results from Hg analysis by CVAA (detection limit of 0.00001 mg/L) with ultra-trace Hg analysis by CVAFS (detection limit of 0.00000004 mg/L).

Assessment of QA / QC data indicated good data quality for the HC leachates. Results of the QA / QC analyses included the following observations:

- Method blanks were consistently below detection limits.
- Duplicate analyses were generally acceptable (RPD typically less than 20%), with occasional higher RPDs limited to concentrations near detection limits.

[7] Ultra-trace analyses were conducted on the leachates to supplement and corroborate the very low concentrations (typically below the analytical detection limit of 0.00001 mg/L) previously determined by CVAA.

- Charge balance results were typically within +/- 15% for samples. Larger imbalances are attributed to near-detection limit uncertainty.
- Consistently higher alkalinity concentrations in several humidity cell leachates were observed for data in week 29 of the test. Alkalinity concentrations returned to the previous baseline for each cell in the following week.
- pH for weeks 54 and 107 for HC-33 and HC-13, respectively, was omitted due to quality assurance issues.
- ICP-S vs sulphate-S results displayed a good agreement (typically within +/- 15%). Larger differences at low concentrations were attributed to the elevated sulphate and sulphur detection limits (0.2 to 2 mg/L for sulphate, 3 to 5 mg/L for sulphur) or near-detection limit uncertainty.
- Hg results displayed good agreement between the compared methods whereby all the results from CVAFS were below the detection limit for CVAA (<0.00001 mg/L).
- Data collected at weeks 10 and 29 for HC-6 and week 59 for cell HC-3 were excluded due to isolated deviations from the testing protocol, specifically involving the addition of water volume exceeding protocol specifications and / or the absence of leachate filtration.

5.4.4 RESULTS

Humidity cell test results are presented in Table D-1 through Table D-35 and Figure D-1 through Figure D-148 in Appendix D. Figures are grouped by rock type for ease of review.

Concentrations of several parameters including Hg (CVAA; detection limit of 0.00001 mg/L), Ag (detection limit of 0.00005 mg/L), and Cr (detection limit of 0.00008 mg/L) were generally at or near the analytical detection limit throughout the duration of testing. Ongoing humidity cell testing is utilizing ultra-trace detection limits for Hg (0.00000004 mg/L). Four weeks of data are currently available and ultra-trace Hg analyses continues.

Results for key parameters are summarized below based on the available data.

- Leachates from 29 of the 35 cells had a circumneutral pH, with pH levels around pH 6.5 to 7.4 in recent data (Figures D-1 to D-4). Of the 29 circumneutral cells, two FV samples (HC-31, and HC-32) displayed slightly decreasing pH trends in recent data. The other 27 cells, including all Basalt and Fragmental lithologies, 15 Felsic Volcanic and four Metasediment samples displayed generally stable pH in recent data. Acidic to weakly acidic pH conditions (on the order of approximately pH 4.5 to 6.2) were observed in six PAG cells that had elevated sulphide content and a low NP content, including three Felsic Volcanic cells (HC-4, HC-9, HC-33), two Metasediment cells (HC-14, HC-17), and one Argillite cell (HC-26). These tests have operated over the long term (63 to 109 weeks of data).
- Leachate pH for HC-4 and HC-9 (FV1; PAG, High S, Very Low NP) showed gradual pH decline, becoming net-acid generating (i.e., pH consistently <6.5) after approximately 40 weeks and stabilizing at pH 5.0 to 5.6. HC-33 (FV1; PAG, High S, Very Low NP) remained weakly to moderately acidic (around pH 4.8) since early testing. These cells have high sulphide (>2 wt.%) and low NP (5 to12 kg $CaCO_3$/t) and represent a minor portion of the mine volume.
  - HC-14 (MS2; PAG, High S) showed a slow and steady decline, dropping below pH 6.5 after 76 weeks and ranging between 6 and 6.4 in recent data. After 35 weeks of testing, HC-17 (MS3; PAG, High S, Very Low NP) showed a steady decline to below pH 6.5 after 56 weeks, with recent pH values between 5 and 5.4.
  - HC-26 (Argillite; PAG, High S) showed erratic pH values that were consistently below pH 6.5 after 63 weeks of testing. Recent pH values ranged between pH 4 and 5.
- Acidity release rates were derived from near or below detection limit concentrations (2 mg $CaCO_3$/L) for 28 of the 35 cells throughout the test period (Figures D-9 to D-12). Acidity release rates were based on detectable values in the order of 0.1 to 10 mg $CaCO_3/m^2$/week for six cells with an elevated sulphide content (approximately 1 to 7% sulphide S) that had weakly acidic to acidic pH values in recent data, including HC-4 (FV1; PAG, High S, Very Low NP), HC-9 (FV1; PAG, High S, Very Low NP), HC-14 (MS2; PAG, High S), HC-17 (MS3; PAG, High S, Very Low NP), HC-26 (Argillite; PAG, High S), and HC-33 (FV1; PAG, High S, Very Low NP). One cell (HC-15; PAG, High S) had detectable acidity release despite circumneutral but variable pH values

in recent data. Increasing trends in acidity release for these cells were generally consistent with trends in decreasing pH and alkalinity.

- Alkalinity release rates were in the order of 0.03 to 0.3 mg $CaCO_3/m^2$/week (Figures D-13 to D-16). Of the 35 humidity cell tests, 21 cells representing samples from all rock types had relatively steady alkalinity release rates in recent data, whereas 14 cells showed decreasing trends in alkalinity release. Seven of these cells with steady alkalinity release had alkalinity release rates based on concentrations at or near the detection limit, including HC-1 (FV1; PAG, High S), HC-4 (FV1; PAG, High S, Very Low NP), HC-9 (FV1; PAG, High S, Very Low NP), HC-14 (MS2; PAG, High S), HC-17 (MS3; PAG, High S, Very Low NP), HC-26 (Argillite; PAG, High S) and HC-33 (FV1; PAG, High S, Very Low NP). Non-detectable alkalinity release was associated with cells that had weakly acidic to acidic leachate pH, as expected.
- Sulphate release rates for most cells declined after start-up and stabilized between 0.004 and 0.5 mg/m^2/week (Figures D-17 to D-20). Felsic volcanic cells (e.g., HC-4, HC-9, HC-33) showed relatively stable sulphate release despite decreasing pH and detectable acidity. Metasediment cells (HC-14, HC-15, HC-17) exhibited increasing sulphate release in recent data, coinciding with pH decline and acidity release. Argillite (HC-26) had the highest sulphate release (up to 2.7 mg/m^2/week), with erratic trends that generally increased from week 20 onward.
  - A relationship between solid phase total S content and sulphate release rate was observed for the samples, as shown in Figure 5.4-1. Sulphate release rates generally showed an increasing trend with total S content for the samples. Sulphate release rates were higher for HC-26 (Argillite; PAG, High S) relative to other samples with a similar total S content, attributed to the elevated pyrrhotite content identified by R-XRD and QEMSCAN (5.6 and 16 wt.% respectively, Table 5.4-3) of this sample.
  - As shown in Figure 5.4-1, NPAG samples (with a lower total S content) generally had lower sulphate release rates relative to PAG samples. However, some PAG samples with a low total S content had similarly low rates of sulphate release as the NPAG samples. Higher sulphate release rates were generally associated with samples with a higher total S content, represented by the PAG samples in the data set.
  - Sulphate release rates were based on detectable sulphate concentrations for most humidity cell tests. Three NPAG cells (HC-6, HC-7 and HC-34) had sulphate release rates that were primarily based on detection limit-derived values [8] (i.e., 0.2 mg/L). The low observed sulphate release rates are attributed to low sulphide oxidation rates for these cells in the current data (Figure 5.4-1).
- Release rates for As varied from 0.000004 to 0.002 mg/m^2/week among the test samples. Release rates for most cells showed steady to steadily decreasing trends (Figures D-33 to D-36).
  - Most samples with a typical [9] As content generally had lower As release rates than samples with a higher As content. However, several samples with a relatively low solid phase As content, including HC-7 (FV1; NPAG), HC-16 (MS2; PAG, Typical S), HC-18 (MS3; NPAG), HC-21 (Basalt; NPAG, Typical S), HC-29 (FV1; CarbNPR 1 to 2), HC-31 (FV1; CarbNPR 1 to 2), and HC-35 (Frag2; PAG, Typical S, Very Low NP) had As release rates that were similar to samples with a higher solid phase As content. Samples with a higher solid phase As content included HC-2 (FV1; CarbNPR 1 to 2, Typical S), HC-15 (MS2; PAG, High S), HC-23 (Basalt; NPAG, High S), and HC-30 (FV1; CarbNPR 1 to 2, Typical S). These samples had a solid phase As content that was >90th percentile relative to their respective lithologies in the ML / ARD database, with 160 to 5,100 mg/kg As.
  - There was a reasonably consistent relationship between the solid phase As:S molar ratio and As release rates for most samples; in general samples with a lower As:S molar ratio had lower As release rates. This suggested that As host mineralogy is an important consideration in As leaching from the samples.

[8] Median sulphate release rates were based on at or below detection limit-derived values if more than 50% of the results in the last 10 weeks of testing showed sulphate concentrations that were at or below the analytical detection limit.
[9] The term typical refers to values >40th to <75th percentile range relative to the samples of a specific lithology in the ML / ARD database.

  - Relatively low concentrations of the sulpharsenide mineral gersdorffite-cobaltite (or an undifferentiated As sulphide phase) were identified by QEMSCAN (Section 5.3; Table 5.4-3) for some isolated samples that had a relatively low solid phase As content but a higher-than-expected As leaching rate. Based on the currently available data, it is likely that the low As content humidity cell samples with higher As release rates contain gersdorffite-cobaltite, which gives rise to the observed higher As release rates for these samples. Due to the low abundance of these phases, they are not directly reflected in the bulk As and S composition of these samples. It is noted that sulpharsenide phases are currently understood to have a limited presence among the overall Project rock.

- Release rates for Se showed a steady to steadily decreasing trend over the test period for most samples (Figures D-37 to D-40). Se release rates varied among the tests and were on the order of 0.0000008 mg/m^2/week (based on detection limit-derived concentrations of 0.00004 mg/L) to approximately 0.00004 mg/m^2/week in recent data. Increasing Se release trends were observed in recent data for a number of cells that displayed an increase in sulphate and acidity release (Felsic volcanic cell HC-9, and Metasediment cells HC-14, HC-15 and HC-17) which was generally concurrent with decreasing pH. A relationship between solid phase Se content and Se release rate was observed, whereby samples with a higher Se content had higher Se release rates. Most samples with a typical solid phase Se content relative to their respective lithologies in the ML / ARD database had low Se release rates that were often based on the analytical detection limit. Samples with a higher sulphide content often had higher Se release rates, attributed to Se substituting for S in sulphide minerals (e.g., pyrite).
- Release rates for Zn were consistently low for most cells, on the order of 0.00005 mg/m^2/week and were typically based on detection limit-derived concentrations (0.002 mg/L, Figures D-41 to D-44). Zn release rates for several cells including HC-1 (FV1; PAG, High S), HC-17 (MS3; PAG, High S, Very Low NP), HC-26 (Argillite; PAG, High S), and HC-33 (FV1; PAG, High S, Very Low NP) were elevated relative to the other cells (0.0003 to 0.003 mg/m^2/week). Zn release rates for HC-4 (FV1; PAG, High S, Very Low NP) and HC-9 (FV1; PAG, High S, Very Low NP) were notably elevated relative to other cells (0.05 to 0.2 mg/m^2/week, Figure D-41).
  - Overall higher Zn release rates for HC-1, HC-4, HC-9, HC-17, and HC-26 were attributed to their elevated Zn content (on the order of 270 to 34,000 mg/kg, Table 5.4-2) and progression to acidic conditions (pH less than 6) in cells HC-4, HC-9, HC-17 and HC-26. Zn release rates for HC-33 (32 mg/kg Zn) were greater than other cells with a similar Zn content and this was attributed to the acidic pH observed in this cell.
  - Sphalerite was identified by R-XRD and QEMSCAN in HC-1 (0.7 and 1.3 wt.%), HC-4 (1.1 and 2.3 wt.%), and HC-9 (5.1 and 6.7 wt.%), although the samples also contained pyrite (Table 5.4-3). Trace sphalerite was also identified in cell HC-17 (0.02%) and HC-26 (0.19%) using QEMSCAN.
  - Release rates for Cd showed similar patterns to Zn release rates, attributed to the release of Cd substituted for Zn in sphalerite. Release rates for Cd were generally low for most cells (on the order of 0.0000001 mg/m^2/week and based on at or near the analytical detection limit concentrations of 0.000003 mg/L).
  - Cd release rates were higher for cells with an elevated Cd content including HC-1 (FV1; PAG, High S), HC-4 (FV1; PAG, High S, Very Low NP), HC-9 (FV1; PAG, High S, Very Low NP), HC-17 (MS3; PAG, High S, Very Low NP), and HC-26 (Argillite; PAG, High S) which represented ≥95th percentile Cd content relative to their respective lithologies among the ML / ARD database (approximately 1 to 200 mg/kg Cd, Figures D-45 to D-48). Increased Cd release rates were concurrent with decreasing pH trends and the development of weakly acidic conditions (pH <6.5) in these cells.
- Release rates for Pb were consistently low for most cells, on the order of 0.000002 mg/m^2/week and were typically based on detection limit-derived concentrations (0.00009 mg/L, Figures D-49 to D-52). Pb release rates for several cells including HC-1 (FV1; PAG, High S), HC-4 (FV1; PAG, High S, Very Low NP), and HC-9 (FV1; PAG, High S, Very Low NP) were elevated relative to the other cells.
  - Pb release rates were relatively steady at 0.001 mg/m^2/week for HC-1 over the first 50 weeks of testing, and after decreased toward 0.0005 mg/m^2/week. Release rates for Pb in HC-9 steadily increased to values of approximately 0.01 mg/m^2/week after 80 weeks of testing.

Similarly, Pb release rates for HC-4 increased to approximately 0.01 mg/m^2/week after week 60 (Figure D-49).

  - Release rates for Pb in HC-17 were based on detection limit concentrations for the first 90 weeks of testing, after which Pb release rates showed a slightly increasing trend toward 0.000006 mg/m^2/week in recent data.
  - These trends were consistent with decreasing trends in pH and / or the development of acidic to weakly acidic conditions in these cells. Higher Pb release rates for HC-1, HC-4, and HC-9 were attributed to their elevated Pb content (910 to 6,200 mg/kg, representing ≥95th percentile Pb content among the FV1 samples in the ML / ARD database).

- Release rates for Ni were low and stable for most cells, on the order of 0.000003 mg/m^2/week and were typically based on detection limit concentrations (0.0001 mg/L, Figures D-53 to D-56). Several cells had higher Ni release (0.000005 to 0.002 mg/m^2/week) including HC-4 (FV1; PAG, High S, Very Low NP), HC-9 (FV1; PAG, High S, Very Low NP), HC-14 (MS3; PAG, High S), HC-15 (MS2; PAG, High S), HC-17 (MS3; PAG, High S, Very Low NP), HC-26 (Argillite; PAG, High S), and HC-33 (FV1; PAG, High S, Very Low NP). While some of these cells had elevated solid phase Ni contents (e.g., HC-9, HC-15 and HC-26), solid phase Ni concentrations were lower for other samples and trends in Ni release were attributed to the development of acidic to weakly acidic leaching conditions in these cells (e.g., most recently, HC-14). HC-15 (MS2; PAG, High S) has exhibited sustained high release rates for Ni (0.002 mg/m^2/week) since week 88. Leachates for this cell had a neutral pH and elevated Ni release was attributed to the high Ni content of the test sample (6,100 mg/kg, 100th percentile among the ML / ARD database and contained gersdorffite-cobaltite).
- Release rates for Co were low and stable in most cells, ranging from approximately 0.0000001 to 0.000002 mg/m^2/week in recent data (Figures D-57 to D-60). Release rates for Co were elevated (up to 0.0002 mg/m^2/week) and / or displayed increasing trends typically in cells that developed acidic to weakly acidic conditions, including HC-4, HC-9, HC-14, HC-17, HC-26, HC-33. Alternatively, Co release rates were higher (0.0000001 mg/m^2/week) for a neutral leaching cell with a very high Co content, HC-15 (100th percentile solid phase Co content relative to the MS2 samples in the ML / ARD database, 400 mg/kg). This sample had the highest gersdorffite-cobaltite abundance among all humidity cell samples (approximately 1%).
- Release rates for Hg were based on concentrations at the analytical detection limit (0.00001 mg/L by CVAA analysis) for all the humidity cell tests over the duration of testing (Figures D-61 to D-64).
- Ultra-trace Hg analysis (determined through CVAFS) confirmed the very low release rates of Hg (less or equal to 0.0000002 mg/m^2/week) in the samples as initially determined by CVAA.

5.4.5 LAG TIME TO ACID ONSET FOR HUMIDITY CELL TESTS

The time to depletion of sulphide and NP in the humidity cells was estimated to provide guidance on the time to acid onset for PAG Project rock.

Release rates for S were calculated from the last 10 weeks of available data for all humidity cell tests. Neutralization potential loss rates were calculated by two methods, depending on the cell's CMR, represented by the molar release of Ca, Mg and sulphate as (Ca+Mg)/SO_4 in the leachates.

  - For cells with a CMR >2, NP dissolution was interpreted to be enhanced under test conditions, due to the weekly flushing of the cell with weakly acidic deionized rinse water. Therefore, S release rates were used to estimate NP loss rates, assuming a 1:2 ratio of AP production and NP consumption.
  - For cells with a CMR 1 to 2, NP dissolution was interpreted to occur mainly due to sulphide oxidation. Neutralization potential loss rates were directly calculated based on Ca and Mg release for these cells.
  - For cells that appeared to have sulphate release influenced by the oxidation of non-acid generating sulphide minerals, weekly sulphate release rates (and CMR values) were corrected via mass balance approaches to account for sulphate produced from the oxidation of acid generating sulphide minerals only. This correction was conducted for HC-9, which had a mixed sulphide mineralogy including acid generating and non-acid generating sulphides,

and a notable amount of sulphate release (20 to 30%) that appeared to be generated from the oxidation of non-acid generating sulphides (mainly sphalerite, minor galena) before the observed acid onset. During neutral leachate pH conditions, sulphate release rates for other samples that contained non-acid generating sulphides appeared to have a negligible proportion of their sulphate release (e.g., <3%) associated with non-acid generating sulphide oxidation.

  - Loss of S and NP during the overall test period was similarly determined based on the above approaches.

- CarbNP was used as the measure of available acid neutralization capacity in the samples for assessment purposes. Given the low sulphide oxidation rates observed for some samples, it is possible that some of the non-carbonate NP present in the samples may also be able to provide some effective NP.

Estimated lag times are presented in Table 5.4-4. Observed lag times are provided for cells that became net-acid generating during testing.

Fifteen of the 20 Felsic Volcanic samples were PAG. Overall, cells with a more typical S content generally showed low rates of sulphide oxidation in the humidity cell tests, which resulted in prolonged estimates of lag times to acid onset. Kinetic test results to date indicate the following lag times:

- One cell, HC-19, had a very low NP content (5 kg $CaCO_3$/t) and a low S content (0.2%) and was estimated to become net acid generating in approximately 90 years based on the currently available data. Sulphide oxidation rates for this cell were very low, with sulphate release rates based on concentrations that were near the analytical detection limit.
- Cells with a moderate S content (e.g., 1 to 3%) and relatively low NP content (approximately 5 to 10 kg $CaCO_3$/t) including HC-1, HC-12 and HC-13 had low sulphide oxidation rates in the humidity cell tests and lag times were on the order of one to two decades.
- Cells with a higher NP content (e.g., ≥20 kg $CaCO_3$/t) had lag times estimated to be approximately 100 years or longer. Lag times greater than 100 years were also estimated for cells that had a lower NP content (approximately 5 to 10 kg $CaCO_3$/t) that contained low S levels, including HC-3 (0.4% S) and HC-29 (0.16% S).
- Cells with very low NP and a high S content relative to the FV samples in the ML / ARD database, including HC-4, HC-9 and HC-33 (CarbNP <2 kg $CaCO_3$/t) became net-acid generating during the test period: HC-4 and HC-9 became net-acid generating after 40 weeks of testing and HC-33 was net-acid generating upon test start-up. The differences in lag times for these cells is hypothesized to be related to their mineralogy.
  - HC-33 contained only acid generating sulphide minerals (i.e., pyrite and pyrrhotite) while HC-4 and HC-9 contained acid generating and non-acid generating sulphides (i.e., pyrite, sphalerite, and galena). The presence of non-acid generating sulphides in HC-4 and HC-9 may have also reduced the reactivity of pyrite through galvanic interactions. While non-acid generating sulphides are present in some samples, they do not appear to be prevalent, and they may not be the reason for the observed lower sulphide oxidation rates among all the samples.

Similar patterns were observed for other rock types:

- All three MS2 samples were PAG (HC-14, HC-15 and HC-16).
  - Leachate from sample HC-14 became weakly acidic (pH between 6 and 6.5) after approximately 80 weeks of testing. This sample had low CarbNP determined by ABA (4.7 $CaCO_3$/t), moderate sulphur (1.2%) and moderate sulphate release rates in comparison to other samples. Of note, CarbNP determinations using QEMSCAN data (1.8 kg $CaCO_3$/t) was notably lower than CarbNP determined by ABA.
  - Lag times to acid onset were estimated to be 14 years for HC-16, based on low sulphate release rates and relatively low S (0.6%), despite the relatively low CarbNP content of this sample (approximately 3 kg $CaCO_3$/t).
  - HC-15 had one of the highest NP and S contents among the MS2 samples in the ML / ARD database (CarbNP 60 kg $CaCO_3$/t and 5.6% S) and had an estimated lag time of approximately 40 years.

- Two of the three MS3 samples were PAG (HC-17 and HC-28). HC-17 had a very low CarbNP content (0.7 kg $CaCO_3$/t) and a high S content relative to the MS3 lithology in the ML / ARD database (1% S) and became net-acid generating after 56 weeks of testing. HC-28 had typical NP and S contents relative to the MS3 samples in the ML / ARD database (CarbNP 3 kg $CaCO_3$/t and 0.2% S) and had an estimated lag time to acid onset of 76 years.
- One of the six Basalt samples was PAG (HC-25) and had an estimated lag time of 76 years. The NP content of the PAG Basalt sample was typical among the Basalt samples in the ML / ARD database (approximately 45 kg $CaCO_3$/t).
- The Fragmental 1 and Fragmental 2 samples (HC-27 and HC-35) were both PAG with lag times to acid onset estimated to be in the order of 29 and 32 years, respectively.
- The Argillite sample (HC-26) was PAG with an anomalously high (8.5%) sulphide content. Cell leachates initially became acidic after 43 weeks of testing and became fully acidic after 63 weeks. This cell had a CarbNP content on the order of 20 kg $CaCO_3$/t, and was previously estimated to have a lag time on the order of several years. While sulphate release rates did increase since the previous update (which affects lag time estimates), test results also suggest that only about 15% of the sample's CarbNP (mainly identified as calcite by R-XRD) was utilized prior to the onset of net-acid generating conditions. This suggests that a proportion of the measured NP in this sample may have been unavailable for neutralization (or at a minimum not able to react sufficiently rapidly to neutralize acidity generated from this high pyrrhotite content sample). Notably, mineralogical examination of this sample identified calcite contents (QEMSCAN 0.35 wt.%, or 3.5 kg $CaCO_3$/t; R-XRD 1.3 wt.%, or 13 kg $CaCO_3$/t) that would represent lower effective CarbNP values that would correspond more closely to the observed lag time.

Six samples had a total S content of 0.15% or less (HC-6, HC-7, HC-18, HC-22, HC-24 and HC-35), which represents the lower total S content threshold to separate PAG and NPAG for the Project (Section 5.2.5).

- Five of the six samples (HC-6, HC-7, HC-18, HC-22 and HC-24) were NPAG by ABA testing. Kinetic testing also indicated that these samples were NPAG when their release rates and estimated lag times to sulphide and NP depletion were considered.
- One sample (HC-35) with a S content of 0.13% was classified as PAG by ABA testing (CarbNPR <1). The sample contained very little CarbNP (2.7 kg $CaCO_3$/t) but had an NPR>2 owing to the presence of non-carbonate NP (Modified NP of 16 kg $CaCO_3$/t, including 30 to 40% plagioclase identified by mineralogical testing).
    - Humidity cell test results indicated that CarbNP loss was enhanced by the test procedure (CMR value of approximately 10). Therefore, to be consistent with the approaches used for other cells, CarbNP release as a result of acid-neutralization was estimated as two times the acid potential release rate; however, the actual CarbNP loss could be lower than estimated. Sulphate release rates were also slightly above the detection limit, and it is expected that non-carbonate NP may also be available for neutralization in this sample. Static test results indicated that non-carbonate NP may be available for neutralization in similar samples (see Section 5.2.5.
    - Considering the estimated NP loss rate and conservatively assuming only CarbNP is available for neutralization, results suggest the sample is PAG with a lag time of 32 years; at that time, it is estimated that the sample would contain less than 0.09% sulphur. If a small portion of the non-carbonate NP is effective (approximately 30%) the sample would be classified as NPAG based on the humidity cell test results. Considering the observed low sulphide oxidation rates, it is expected that at least some of the non-carbonate NP will be effective. Ongoing studies will confirm the performance of low sulphur materials.
- Seven humidity cell tests (HC-2, HC-10, HC-25, HC-29, HC-30, HC-31 and HC-32) had an NPR between 1 and 2 and results were reviewed in the context of developing a site-specific NPR value. Evaluation of the test results indicated that the dissolution of NP in these cells was driven by weakly acidic rinse water in the test procedure, rather than in response to sulphide oxidation, under current test conditions. Therefore, an NPR of 2 is still recommended based on the current data.

5.4.6 KEY FINDINGS

Interpreted Lag Time to Apply for Mine Planning

Lag time relationships were developed for PAG Project rock based on the available humidity cell test results (63 to 109 weeks). These were based on the observed relationship between sulphide oxidation rate and S content in the samples. A relationship was derived that relates total S content (expressed as MPA) with acid potential release and lag time to acid onset.

All PAG Rock, Except Argillite

As discussed in Section 5.4.4, a relationship between sulphate release rate and solid phase S content was observed, whereby samples with a lower solid phase S content appear to have lower sulphide oxidation rates. This suggests that a sample's S content will influence the rate at which AP is produced, and consequently the rate at which NP is consumed and the resulting lag time to net-acidification of the sample. A lag time relationship was determined as follows:

- Sulphate release rates were converted to acid potential release. A relationship between S content (expressed as MPA) and acid potential release was represented by an equation that was fit to the upper-most datapoints (Figure 5.4-2) in order to estimate the minimum time to acid onset.
- Acid potential release rates were used to estimate NP loss rates, assuming a 1:2 ratio of AP production to NP consumption. Equations are provided in Table 5.4-5 to calculate lag times based on the above considerations.

As described herein, a few samples contained mixed sulphide mineralogy with acid generating sulphides (pyrite, pyrrhotite) and non-acid generating sulphides present (mainly sphalerite) in some samples. The sulphate release rates used to express acid potential release were adjusted for one sample (HC-9) which was markedly influenced by sphalerite oxidation. While this adjustment was made for one of the samples, the presence of sphalerite in the Project rock is currently understood to be minor, and galvanic interactions between sulphides are not anticipated to notably impact the overall lag time estimates.

PAG Argillite

The Argillite test sample (HC-26) had higher AP (sulphate) release rates than other humidity cell tests with a similar S content (Figure 5.4-2). This was attributed to the elevated pyrrhotite content of the sample (Table 5.4-3), resulting in it being more reactive than other test samples.

Other Argillite samples (n=10 samples) tested as part of ongoing baseline studies for the Project showed similar geochemical characteristics and sulphide mineralogy. Therefore, data from HC-26 was used to represent Argillite materials for the purposes of this assessment. Acid potential release was calculated from the sulphate release rate and NP consumption was estimated assuming a 1:2 ratio of AP production to NP consumption. A lag time relationship for Argillite is provided in Table 5.4-5.

Based on the Project block model, Argillite represents a very minor rock type (<1% of the mine volume). Information from the block model indicates that Argillite blocks have a median S content of 0.3%. This suggests that the Argillite sample in the humidity cell test (S content of 8.5%) is not representative of the bulk of the Argillite associated with the mine development. Argillite with 8.5% sulphur represents the 91st percentile amongst collected Argillite drill core samples that were submitted for ABA testing (n=11). Therefore, this lag time estimate for Argillite is likely not representative of the bulk of this rock type and will ascribe a much shorter lag time to net acidic conditions than will be experienced by the bulk of the Argillite rock.

Lag Time Relationships

The lag time relationships shown in Table 5.4-5 will be applied in the ARD block model to estimate PAG rock characteristics and guide mine rock management. These estimates are based on currently available results of the humidity cell tests (63 to 109 weeks of test data). Lag times will continue to be assessed as additional humidity cell test data becomes available.

Uncertainties in the estimated lag times increase with decreasing CarbNP values. Lag time equations also assume that CarbNP is the only reactive source of NP in the rock and that all CarbNP is readily available for neutralization. If some of the CarbNP is not available, or non-carbonate NP provides an effective source of buffering (particularly for lower S content samples with low rates of sulphide

oxidation), the above equations may require modification to account for these factors. Humidity cell testing is continuing to assess the performance of these materials.

For the purposes of these estimates, it was assumed that rates of sulphide oxidation in the humidity cells were representative of sulphide oxidation rates for Project rock in the field. However, in northern environments field oxidation rates are generally slower than laboratory measured rates. Lower temperatures during the winter months may slow oxidation rates and extend the lag times (MEND 1.61.6); scaling differences (particle size differences) between laboratory samples and field Project rock may further extend the duration until net-acidic conditions occur. Field kinetic test data (Section 5.6) suggest that oxidation rates may be five to ten times slower under field conditions relative to measured laboratory rates.

Overall, the humidity cell test data suggest that Project materials may have a range of lag times:

- Low sulphide oxidation rates in typical pyrite- and pyrrhotite-bearing materials leading to long lag times (10 years or longer).
- Low sulphide oxidation rates in high sulphide, low NP materials with accessory sulphides (e.g., sphalerite, galena).
- Acidification within a limited timeframe in high sulphide, low NP samples. This material is currently understood to represent a minor component of the overall Project rock.

In general, sulphide oxidation rates were low for most samples. Trace metal substitution in pyrite / pyrrhotite may play a role in the observed low rates of sulphide (pyrite / pyrrhotite) oxidation and are currently being assessed in detailed mineralogy programs. Galvanic interactions may also be influencing sulphide oxidation rates, but given the current mineralogical dataset, the prevalence of non-acid generating sulphides is thought to be limited and therefore not notably affecting the observed low sulphide oxidation rates. Kinetic testing continues to be routinely monitored.

Site Specific Neutralization Potential Ratio

Humidity cell test results were also interpreted to support an assessment of developing a site-specific NPR threshold for Project rock. The standard thresholds for PAG and NPAG mine rock listed in MEND (2009) include NPR ≤1 is PAG, NPR >2 is NPAG, and materials with an NPR 1 to 2 having an uncertain acid generating potential. Humidity cell testing of materials with an NPR between 1 and 2 can be used to support further refinement of the NPR threshold between uncertain and NPAG through evaluation of sulphide and NP reaction rates in humidity cell tests.

Seven humidity cell tests had a CarbNPR between 1 and 2 (Table 5.4-2) for which results were reviewed in the context of developing a site-specific NPR value.

- The CMR values (i.e., molar ratio of $Ca+Mg/SO_4$) for these cells were greater than two (on the order of 5), indicating that the dissolution of NP in these cells was driven by the weakly acidic rinse water in the test procedure, rather than solely in response to sulphide oxidation.
- Due to this, depletion time estimates for these samples were prepared based on the acid potential release and theoretical NP release (assuming 2:1 NP to AP release).
- Based on the response of the samples in the humidity cell tests, an NPR of 2 is still recommended as the threshold between PAG and NPAG rock.

Site Specific Total S Threshold

A total S content of 0.15% represents the threshold for distinguishing PAG and NPAG for the Project. This criterion was developed through review of static test results (Section 5.2.5) and compared to kinetic test data.

Five out of the six humidity cell tests with a total S content of 0.15% or less were NPAG by ABA using CarbNP. Kinetic testing results confirmed these samples were estimated to be NPAG.

One cell with 0.13% sulphur (HC-35) was classified as PAG by CarbNPR but contained a notable proportion of non-carbonate NP and had an NPR >2.

Test results indicated that CarbNP loss was enhanced by the test procedure so CarbNP loss was estimated as two times the acid potential release rate for assessment purposes. The estimated CarbNP loss rates suggested that the sample was PAG with a lag time of 32 years if only CarbNP was available for neutralization. However, CarbNP loss rates due to sulphide oxidation may be lower

than estimated and it is likely that non-carbonate NP will be a source of neutralization given the observed low sulphide oxidation rates in the sample. Humidity cell test results indicated that if a small proportion of the non-carbonate NP was effective at neutralizing acidity the sample would be NPAG. Further, other samples with a TS <0.15% have shown consistently low rates of sulphide oxidation suggesting that non-carbonate NP is likely to be a source of effective NP for the samples.

Results of the kinetic tests are supportive of the total S threshold of 0.15%. Ongoing studies will confirm the performance of low sulphur materials.

Metal Leaching

Summarized release rates are presented in Table 5.4-6 for selected parameters. Rates are based on the median release rates observed over the last 10 weeks of testing for cells HC-1 to HC-27 (109 weeks of data available), and over the last 5 weeks of testing for cells HC-28 to HC-35 (63 weeks of data available).

The release rates shown represent circumneutral pH conditions for most cells (except for HC-4, HC-9, HC-14, HC-17, HC-26 and HC-33). In general, metal release rates were relatively low for most metals for test samples representative of material with typical solid phase characteristics relative to the ML / ARD database (i.e., values >40th to <75th percentile range relative to the samples of a specific lithology in the ML / ARD database). Relatively elevated release rates for some cells were often associated with samples with a higher elemental content in the solid phase (see Section 5.4.4) and / or associated to the development of acidic conditions.

Release rates may continue to change over time following acidification of the PAG rock samples, or stabilization of existing acidic leaching conditions where they have begun to develop.

Table 5.4-1: Humidity Cell Study Summary

Rock Type	Rock Type ID	Number of Humidity Cell Tests
Felsic Volcanic 1	FV1	16
Felsic Volcanic 2	FV2	4
Metasediment 2	MS2	3
Metasediment 3	MS3	3
Basalt	Basalt	6
Argillite	S1A	1

Notes:

1 *Release rates based on median release rates for the last 10 weeks of data for all cells. Acid potential release rates based on S release rates. NP release rates estimated from acid potential release rates for cells with a CMR >2, assuming a 1:2 ratio of AP production and NP consumption. Neutralization potential release rates were estimated from Ca and Mg release for cells with CMR 1 to 2.*

2 *Time to AP depletion based on MPA for all cells. Time to NP depletion based on CarbNP. Lag times include consideration for AP and NP release during the test period, and the projected release of AP and NP based on the release rates.*

3 *Neutralization potential ratio based on CarbNPR (CarbNP/MPA).*

4 *These samples contained pyrrhotite and the HCl leach test identified a notable proportion of sulphate S. The sulphide S content of these samples is shown based on total S minus sulphate S for consistency with the other data. However, sulphate minerals were not present in these samples based on R-XRD and QEMSCAN results, and elevated sulphate S is attributed to the dissolution of pyrrhotite in the HCl leach test. The sulphide S value is shown in square brackets [ ] for those samples, in consideration for mineralogical artefacts in the HCl leach test.*

5 *PAG classification is based on consideration of carbonate NP. Sample contains notable non-carbonate NP and has low sulphide oxidation rates. Sample may be NPAG and will continue to be monitored.*

6 *Neutralization potential was based on the modified Sobek NP results for cells that had CarbNP greater than modified Sobek NP values (suggesting the presence of non-net neutralizing carbonates).*

Table 5.4-5: Lag Time Relationships

Rock type	AP Release Rate (kg $CaCO_3$/t/year)	NP Release Rate (kg $CaCO_3$/t/year)	Lag Time Estimate (years)
PAG rock	$MPA^{0.94}$ × 0.0115	$MPA^{0.94}$ × 0.023	CarbNP/($MPA^{0.94}$× 0.023)
Argillite	2.671	5.342	CarbNP × 0.187

Note:
Shaded cells indicate release rates primarily based on detection limit values.

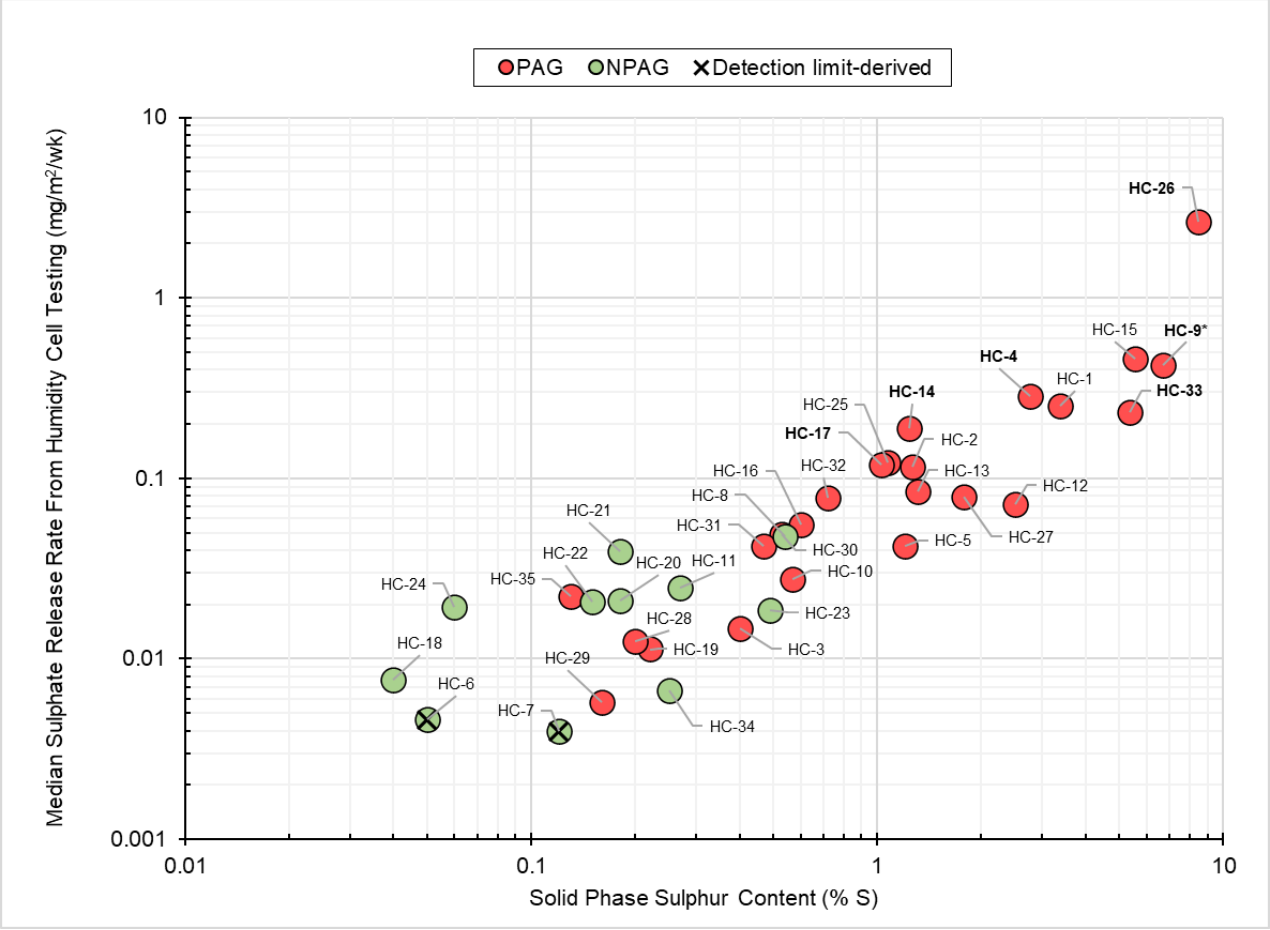

Figure 5.4-1: Relationship between Sulphate Release Rates and Solid Phase Total S Content. PAG and NPAG Classification based on ABA Testing

Notes:
Sulphate release rates are the median of the last 10 weeks of testing for all cells. Bolded labels indicate cells that have become acidic.
HC-9 contains a notable proportion of the non-acid generating sulphide sphalerite. Sulphate release for this cell shows total sulphate released.

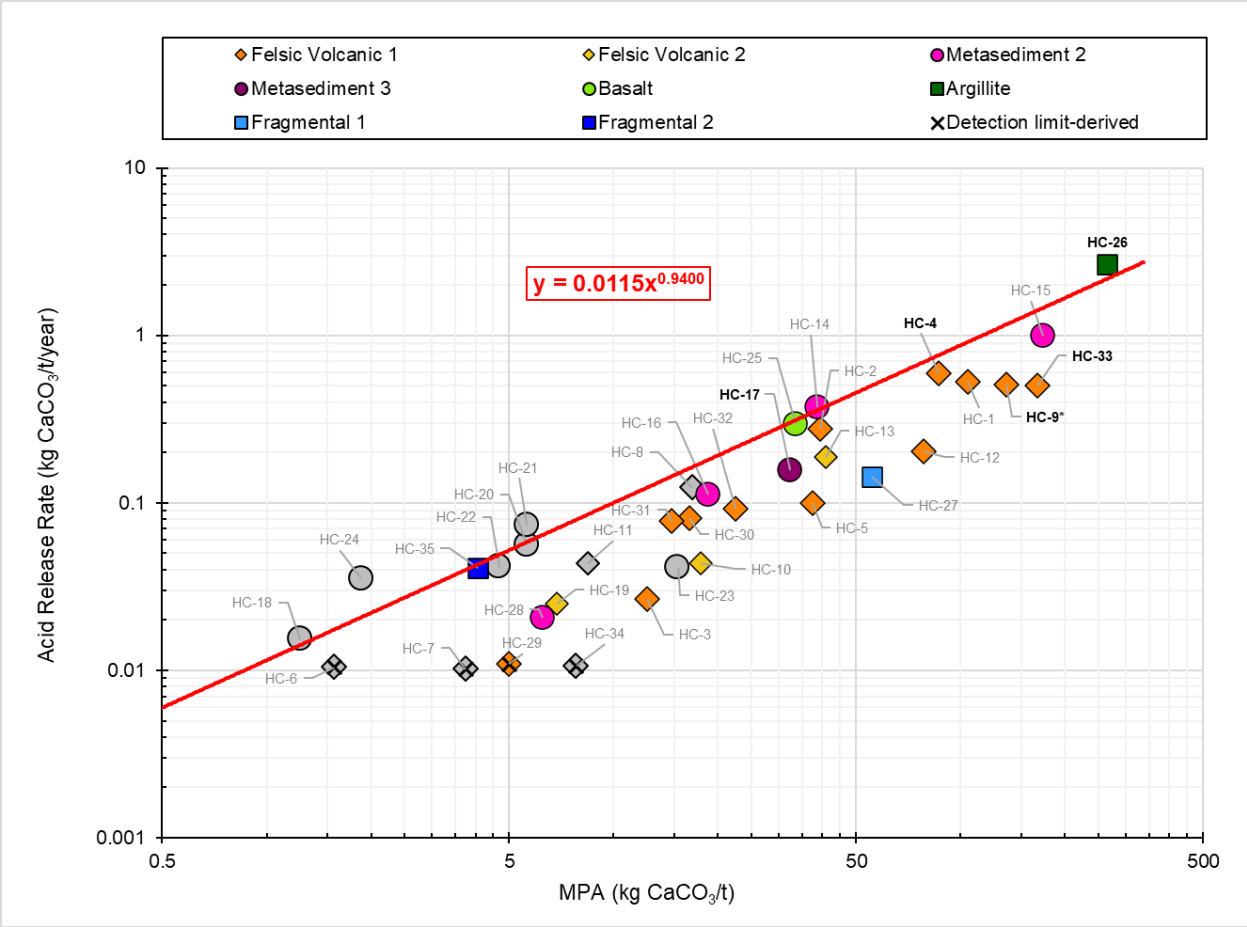

Figure 5.4-2: Relationship between AP Release Rate and MPA of the Test Samples

Notes:
PAG cells shown in coloured symbols. NPAG cells shown in grey.
Release rates are the median of the last 10 weeks of testing for all cells.
Bolded cells became net-acid generating during the test and show pre-acidic AP release rates for lag time estimation purposes.
HC-33 was net-acid generating since test start-up therefore shows the median AP release rate of the last 10 weeks of testing.
Due to the high sphalerite content of HC-9, AP release rates and maximum potential acidity contents for this cell were corrected to represent acid-generating sulphides and associated sulphate release only (see text).

5.5 COLUMN TESTING

5.5.1 OVERVIEW

The column test study for the Project rock included 34 column tests. The test samples were selected to represent key Project rock types in the mine volume as shown in Table 5.5-1. The column test samples included material with a representative range of sulphide, NP and metal contents for NPAG and PAG rock.

Column testing was undertaken to estimate net drainage water quality from test materials.

The results of the column tests are used to inform the Project regarding:

- Neutral metal leaching and NPAG mine rock management requirements.
- Thresholds to guide the segregation and management of metal leaching (ML) and non-metal leaching (NML) rock, if required.

Column testing (Table 5.5-1) was initiated in two stages, including 30 tests (COL-1 to COL-30) initiated in July 2023 and an additional four tests (COL-31 to COL-34) initiated in July 2024, based on static testing on drill core samples (Section 5.2.4). All of the tests operated for a total of 26 weeks per test. COL-1 to COL-30 were terminated in January 2024 and COL-31 to COL-34 were terminated in January 2025. This section contains data reported up to February 2025.

Results of the column tests are discussed in the following sections.

5.5.2 COLUMN TESTING DETAILS

A summary of column testing is provided below. Column testing was conducted at SGS Lakefield following procedures outlined in MEND (2009). Geochemical descriptions of the test samples are summarized in Table 5.5-2. Detailed mineralogical analysis was conducted on all column test samples as presented in Section 5.3.

The 34 column test samples were selected following completion of static testing on drill core samples to represent key rock types in the mine volume (including the overall Project and the AEX Program). The test samples included material with a representative range of sulphide, NP and metal contents. Test samples were selected to represent the range of solid phase concentrations for elements of interest, based on the initial static testing results. This primarily included As, although other sulphide associated elements including Sb, Cd, Co, Cu, Pb, Mo, Ni, Se and Zn were also represented in the sample set. Mercury was not identified as an element of interest based on static testing but was considered for completeness. Other non-sulphide associated elements of interest identified in the static program (Section 5.2.5) including V, P, Cr, W and U were also considered.

Columns were operated as subaerial trickle-leach columns where deionized water is passed through a selected mine rock sample (crushed to <6.3 mm) at a steady rate representing simulated unsaturated porous flow in mine rock. Columns were flushed weekly with approximately 0.30 to 0.35 L of deionized water following an initial flushing procedure to remove any accumulated oxidation products.

Further information regarding test set-up and operation is provided in Section 4.4.2. Representative photos of the columns are provided in Figure 5.5-1.

The column tests were terminated after 26 weeks of operation after the development of steady-state drainage quality. Termination of the column tests included the following:

- Material from each column was removed for archiving and doubled bagged in sealed polyethylene bags with excess air removed.

- Photographs of each of the columns were taken before and after dismantling. Additional testing was not completed at the time of termination.

The finer grain size of the sample material in the columns was interpreted to represent the source of the majority of metal release but is estimated to represent approximately 10% of the rock mass in future stockpiles. The PSD certificates of analysis for the column test samples are shown in Appendix E1. Coarser rock representing the majority of stockpile rock mass is expected to have a materially lower surface area and correspondingly lower rates of metal release. Therefore, 1/10th of the measured column leachate concentration is defined as the scaled leachate concentration for assessment purposes. Unless stated otherwise, leachate concentrations discussed and described hereafter refer to scaled leachate concentrations based on this definition and are presented in Appendix E2.

- Leachate chemistry was used to calculate scaled leachate concentrations based on 1/10th of the measured column leachate concentration. Measured column pH (scaling not applicable) is also included as an indicator in column leaching behaviour and water quality.
- These leachate concentrations were compared to screening values as applicable to provide context to the observed results. It is recognized, however, that the tests are not a direct assessment of mine water quality and comparisons to screening criteria hold no regulatory significance. The screening analysis included comparison of the leachate chemistry to PWQO for the protection of aquatic life, including both in-place PWQO values and interim PWQO values.

Detailed sulphide mineralogy of each sample (Section 5.3) guided interpretation of column leaching results. Elemental contents determined for static testing of the source materials (Section 5.2) were interpreted to represent the potential environmentally available fraction and also provided key reference information for relating leaching observations to the mine rock database.

- For element content, specific consideration was required for As since it was identified to be a priority metal leaching concern and it was also recognized that exploration data and block model results guiding mine rock management were based on four acid concentrations (not aqua-regia).
- In order to interpret site specific metal leaching thresholds and management guidance for As, the four acid elemental contents were used. It was also confirmed that As results by four acid and aqua-regia methods were generally consistent (Figure 5.5-2).

5.5.3 QUALITY ASSURANCE AND QUALITY CONTROL

Upon receipt, column leachate data quality was reviewed. Charge balances, method blanks and method spikes for column testing returned QA / QC data that was within expected benchmarks with rare exceptions that were associated with low leachate concentrations near the analytical detection limit. As noted in Section 5.5.2, column testing included operation of two blank columns as a check on deionized water quality and any interactions with column materials as constructed. Results discussed in Section 5.5.4, confirmed consistently low concentrations from the blank columns that were below analytical detection limits for most elements.

The solid phase geochemical data supporting this work for some column samples have been confirmed in accordance with on-going analytical programs and QA checks with on-going work. Nominal differences were noted in results within expected analytical variability, but the checks did not result in material changes in any metal reference values for the column samples over the course of the study.

5.5.4 RESULTS

Column Leaching

All weekly unscaled (raw) column results are provided grouped by Felsic Volcanic (FV1 and FV2), Metasediment (MS2, MS3 and Argillite), Basalt and Fragmental (Frag2) lithologies in Appendix E3 (Figures E3-1 to E3-132) with steady neutral leaching concentrations for each column provided in Appendix E4. The tabulated leachate concentrations were the median of the last five weeks of steady neutral leaching concentrations. Scaled results are discussed below and presented in Appendix E2.

Results for several parameters including acidity, fluoride, chloride, Hg, Ag, Be, Bi, Fe, P, Ti and Th were generally at or near the analytical detection limit for the duration of the testing. Results for the blank columns were generally at or near the analytical detection limit for the duration of the testing, except for manganese and tin which both had low median (last five weeks) measurable leachate concentrations of approximately 0.00002 mg/L. Steady leaching results (last five weeks) for non-sulphide elements of interest that had concentrations in SFE leachate above screening values including V, P, Cr, W and U (Section 5.5.2) were below screening values for all columns (Table 5.5-3).

Observed leaching trends are summarized below for sulphate and elements of interest related to sulphide oxidation and leaching. Sulphate is included as a measure of relative sulphide oxidation / leaching rates occurring in each sample.

- Sulphate concentrations were generally stable for each column during the test period. Overall, higher sulphide solid phase content columns had higher sulphate leachate concentrations; however, concentrations were generally low ranging from 0.1 to 23 mg/L.
- Metal / element leaching (e.g., Sb, As, Cd, Co, Cu, Mo, Ni, Pb, Se and Zn) exhibited generally steady leachate concentrations for individual columns over the duration of the testing.
- Individual columns with high element solid phase content (e.g., As, Cd, Co, Cu, Pb, Ni and Zn) tended to exhibit initially increasing leachate concentrations that then generally stabilized toward the end of testing. Such samples are not representative of the bulk of the Project rock.

Steady-state pH and leachate concentrations (non-acidic leaching) are presented in Table 5.5-4 for sulphide elements of interest (As, Cd, Co, Cu, Hg, Mo, Ni, Pb, Sb, Se, Zn) and compared to PWQO and interim PWQO screening values. Leachate concentrations are based on the median of the last five weeks of testing at steady pH neutral conditions.

- Most steady-state column leachate concentrations were below the respective PWQO or interim PWQO screening values.
- Elements with leachate concentrations that were greater than the screening values included: As, Cd, Pb and Zn. These elements were above screening values for neutral leaching PAG samples. With the exception of As, these elements were below screening values in NPAG samples. These samples had high solid phase sulphur and metal contents (99th percentile to maximum metal contents) and are expected to represent a very small quantity of Project rock.
- Other sulphide and non-sulphide elements of interest including Sb, Co, Cu, Hg, Mo, Ni, Se, P, Cr, W and U had steady leachate concentrations that were all below screening values in all columns.

The focus of this work was the evaluation of neutral leaching concentrations of NPAG samples and similar neutral leaching of PAG samples at initial pH neutral conditions. However, three low NP and PAG columns including one Felsic Volcanic 2 sample (COL-26) and two Metasediment 2 samples (COL-3 and COL-4) exhibited declining pH toward the end of testing period. These columns decreased to acidic (pH <6.5) conditions. Though humidity cells (not columns) are the accepted standard for assessing carbonate depletion rates, the behaviour of the three PAG columns with declining pH is summarized below.

- The Felsic Volcanic 2 column (COL-26) trended to lower pH near pH 6.4 to 6.6 and approached acidic conditions at week 20. This sample was confirmed to have relatively low calcite content (0.5 $CaCO_3$/t) and relatively high sulphide content of 1.6% S from pyrite and arsenopyrite.
- Leachate from the two other Metasediment 2 samples decreased to acidic conditions (pH <6.5) at week 15 (COL-4) and week 20 (COL-3) and more rapidly than any of the humidity cells described in Section 5.4. Increased sulphate, acidity and some elements were observed for these columns several weeks before or in concert with the decline in pH.
- These Metasediment 2 samples were confirmed to have very low calcite content (0.2 kg $CaCO_3$/t) and relatively high sulphide content, one with 4.7% S from pyrite and one with 1.7% S from pyrite and pyrrhotite. The column with mixed pyrite and pyrrhotite also contained 0.8 kg $CaCO_3$/t dolomite.
- Results for these elevated sulphide and low CarbNP materials align with the depletion time estimates expected based on humidity cell tests (Section 5.4).

Key Parameters

The analyses for parameters and lithologies with leachate concentrations that were above PWQO and interim PWQO screening values are shown in Figure 5.5-3 to Figure 5.5-10.

Results are presented for As in all lithologies. As described above, concentrations above screening values were only observed for Zn, Cd and Pb for isolated PAG samples of Felsic Volcanic that had high sulphur and metal content (99th percentile to maximum solid phase metal content) and are expected to represent a small volume of Project rock.

Results presented include leachate concentration trends for all columns where one or more columns were above the screening values for that lithology. The cumulative frequency distributions of solid phase element content in all static program samples (Section 5.2.5) and each column are included, and a summary of observations are provided below.

Arsenic was above the interim screening value (0.005 mg/L) in the most samples (10 of 34 columns) and included samples for a number of lithologies including Felsic Volcanic 1 (COL-16, COL-18), Felsic Volcanic 2 (COL-17, COL-26), Metasediment 2 (COL-2), Metasediment 3 (COL-5, COL-6), Basalt (COL-7) and Fragmental 2 (COL-33, COL-34) (Table 5.5-4).

- All Felsic Volcanic samples with leachate concentrations above the screening value had elevated solid phase As content (>95th percentile) and are inferred to represent a small volume of Project mine rock (Figure 5.5-3).
- Only one of three Metasediment 2 columns had leachate concentrations above the As screening value and is approximately 80th percentile As solid phase content for Metasediment 2 rock (Figure 5.5-4). Two Metasediment 3 samples were above the screening value and had moderate to elevated As solid phase content at approximately 67th and 84th percentile in comparison to the Metasediment 2 sample. The apparent differences between the Metasediment 2 and Metasediment 3 samples appear to be related to different As mineralogy and is discussed further below.
- Only one of six Basalt columns had leachate concentrations above the screening value (Figure 5.5-5) and the As solid phase content of that sample was elevated (>80th percentile) in comparison to all Basalt samples.
- All Fragmental 2 columns had greater than 85th percentile solid phase As content. The two lower As content samples (COL-33 and COL-34) had As leachate concentrations above the interim PWQO screening value while the two higher As content samples had leachate concentrations at or below the screening value (Figure 5.5-6).

Overall, there was a generally increasing trend in As leachate concentration with increasing As solid phase content in the samples (Figure 5.5-7). However, there was variability among the samples and detailed mineralogy work has been completed to assess As leaching trends. The relationship between As leaching and As host mineralogy is summarized in detail in Section 5.5.5.

Zinc, Cd and Pb leachate concentrations were above the screening value in several Felsic Volcanic samples. Samples with leachate concentrations above the screening values were very high in solid phase sulphur and metals and are understood to represent a minor component of the Felsic Volcanic rock.

- Zinc leachate concentrations were above the PWQO and interim PWQO screening values (0.03 and 0.02 mg/L respectively) for one Felsic Volcanic 1 column (COL-22) which also contained near the maximum Zn solid phase content of Felsic Volcanic 1 samples (e.g., approximately 100th percentile; Figure 5.5-8).
- Cadmium leachate concentrations were above the interim PWQO screening value (0.0001 mg/L) for two Felsic Volcanic 1 samples (COL-13, COL-22) that both represented higher end Cd solid phase content (approximately 99th percentile) of all Felsic Volcanic 1 samples (Figure 5.5-9).
- Elevated Cd (and Zn) solid phase content and leaching for COL-13 and COL-22 is consistent with the presence of sphalerite (Fe,Zn)S identified from detailed mineralogy of these samples.
- Lead leachate concentrations were above the interim PWQO and PWQO screening values (0.001 mg/L and 0.005 mg/L respectively) for one Felsic Volcanic 1 column (COL-13) which also

contained the maximum Pb solid phase content of all Felsic Volcanic 1 samples (100th percentile). Additionally, one Felsic Volcanic 2 column (COL-27) that contained approximately 99th percentile Pb (Figure 5.5-10), was above the interim PWQO screening value (0.001 mg/L).

- Elevated Pb solid phase content and leaching in COL-13 and COL-27 occurs for samples identified as containing galena (PbS) based on detailed mineralogy. The elevated lead leachate concentrations at near neutral pH are somewhat anomalous given the generally expected low mobility of Pb under these conditions although the screening values are also relatively low. Galvanic interaction between galena and other sulphide minerals within the samples (with or without colloidal mobilization) are considered possible explanations for Pb concentrations observed for these columns.

5.5.5 ARSENIC LEACHING

Based on detailed mineralogy findings herein (Section 5.3), the following describes a number of key factors expected to influence As mobility for Project samples and discusses observed sulphide mineralogy in relation to the reported As leaching observations.

Conceptual Description of As Leaching for Project Rock

Due to low solubility of Fe at neutral pH and the importance of Fe oxyhydroxides and other As Fe solid phases in reducing As mobility, the Fe content of sulphide minerals (both Fe As sulphides and non-As sulphides) is a key factor in understanding As mobility in water flowing through mine rock systems. Overall descriptions of the potentially important processes are described below.

- High As retention on Fe oxyhydroxides is generally observed to be limited to a 1:4 As to Fe molar ratio or greater when coprecipitated or sorbed to high surface area forms.
- For pyrite-bound As, it can be inferred that practically all of the As at low solid phase concentration relative to Fe could be readily adsorbed to newly formed Fe oxyhydroxide surfaces upon oxidation of the sulphide.
- During sulphide oxidation of arsenopyrite (FeAsS), a portion of the As can potentially be retained by sorption or coprecipitation with newly formed Fe oxyhydroxide. The 1:1 As to Fe molar ratio of arsenopyrite results in lower Fe availability than the 1:4 ratio and leads to a potential that some As may be released or initial solid phases formed may have lower stability and greater As solubility.
- In contrast to pyrite and arsenopyrite, gersdorffite-cobaltite (Fe,Ni,Co)AsS has a high As content compared to Fe: very little As would be taken up by the Fe oxyhydroxides produced during oxidation of this sulphide. Other minerals may influence and control the solubility of As during oxidation. But these minerals may be amorphous in nature and difficult to detect in the early weathering stages of the mine materials.
- Higher proportions of Fe sulphides (pyrite and pyrrhotite) have the potential to reduce As leaching during oxidation by increasing sorption sites on newly forming Fe oxide / oxyhydroxide surfaces with on-going non-As-bearing sulphide oxidation. Such surfaces can bind As and limit its release if the surfaces are of sufficient quantity and where transport and uptake conditions are favourable. The relative oxidation rates of the As host minerals and the non-As Fe sulphide minerals will also be important.

Arsenic Leaching Results and Sulphide Mineralogy

Arsenic sulphide mineralogy was observed to play a distinct role in As leaching for the column samples. As discussed in Section 5.3.9, mineralogy results indicated the presence arsenopyrite and sometimes gersdorffite-cobaltite solid solutions in the samples as well as variable contents of other sulphide minerals (most often pyrite or mixed pyrite and pyrrhotite). Sometimes an undifferentiated As sulphide (interpreted to be arsenopyrite or gersdorffite-cobaltite) was inferred by QEMSCAN based on low As totals in the analysis.

- Observed As concentrations in leachates above screening values generally occurred in samples with relatively elevated solid phase As content (Figure 5.5-11) and the majority of these samples contain As primarily in the form of arsenopyrite.

- Several samples were observed that leach relatively high concentrations of As with only moderate As solid phase content (Figure 5.5-11), including isolated PAG samples of Metasediment 3 (COL-5, COL-6) and NPAG samples of Basalt (COL-7) and Fragmental 2 (COL-33, COL-34). Detailed mineralogical results have identified these samples as containing primarily As in the form of gersdorffite-cobaltite. These rock types primarily hosted As in pyrite and / or arsenopyrite, and gersdorffite-cobaltite was only present in isolated samples.

As leaching was also more broadly assessed by incorporating leaching results from humidity cell testing.

- The humidity cell steady As loading rates were recalculated as simulated concentrations at the column flow rate. Standard humidity cell operation flushes the cells once weekly whereas columns were operated under a steady trickle leach. However, the total weekly flushed volumes of the columns are relatively similar (0.3 L/kg) compared to the humidity cells (1 L/kg) making this a reasonable comparison.
- Humidity cell results when plotted with column results (Figure 5.5-12) are generally consistent with column results (Figure 5.5-11).

For the combined column and humidity cell sample set, the importance of Fe on As release appears to be evident by comparing the samples' As to sulphide Fe ratio versus their As leaching concentrations (Figure 5.5-13).

- Results indicate an overall increasing trend in dissolved As leachate concentration with increasing As to Fe ratio.
- Rather than following a direct linear trend, the results range from very low As leaching samples with low As to Fe ratios (As in pyrite) to high As leaching samples with higher As to Fe ratios (gersdorffite-cobaltite or arsenopyrite). Results are spread across a band of As to Fe ratios at a given leaching rate. This band is interpreted to be due to multiple Fe As relationships within the samples, varying quantities of low or no As content Fe sulphides (pyrite and pyrrhotite) and likely varying oxidation rates among the various sulphide minerals present.
- The Fe sulphide content of the samples (pyrite, pyrrhotite and arsenopyrite) means that the molar As to S ratio is a generally good measure of the As to Fe ratio. Therefore, the molar As to S ratio (Figure 5.5-14) shows a similar trend as that observed for QEMSCAN sulphide Fe (Figure 5.5-13). Relatively small shifts among samples between the two plots are related to varying sulphide mineral proportions (e.g., pyrrhotite and pyrite that have different Fe to S ratios).

Based on the understanding and observations described above, samples with a high proportion of gersdorffite-cobaltite and little Fe sulphide (pyrite / pyrrhotite) have the highest potential for As leaching. Any gersdorffite-cobaltite that oxidizes and leaches As without concurrently oxidizing pyrite or pyrrhotite will contain insufficient secondary Fe oxyhydroxide surfaces to adsorb As. However, the majority of samples had no gersdorffite-cobaltite detected. This aligned with the observation that aside from several isolated samples, most samples had As concentrations in column leachates that were below screening values.

As leaching from samples with arsenopyrite in the presence of a very low content of Fe sulphides could also occur; however, this was only observed for the high As sample (COL-26, 100th percentile As) which is also PAG and is expected to represent a very small quantity of Project rock.

Lithology Specific Leaching Considerations

Based on the detailed mineralogy results outlined in Section 5.3.6, it is understood that the key As minerals are pyrite, arsenopyrite and gersdorffite-cobaltite.

Most samples had no gersdorffite-cobaltite detected (Figure 5.5-12 and Table 5.5-5). Relatively few samples were observed with gersdorffite-cobaltite detected as a minor phase. Samples with gersdorffite-cobaltite as a minor phase are expected to have As leaching primarily influenced by the primary arsenopyrite or arsenopyrite and Fe sulphide mineralogy. Gersdorffite-cobaltite was identified as the primary As host mineral in some isolated samples.

Detailed mineralogy identified arsenopyrite and Fe sulphides (pyrite / pyrrhotite) as the primary As host mineralogy in all Felsic Volcanic samples (Figure 5.5-12), with some of these samples (COL-16, COL-17, COL-18 and COL-26) above the 0.005 mg/L leachable As screening level when the As solid phase

content was greater than 100 mg/kg. The Felsic Volcanic rock types show little evidence of gersdorffite-cobaltite and much lower potential for As leaching.

While pyrite and arsenopyrite were generally the main As hosts in the Basalt, Metasediment, and Fragmental rock types, gersdorffite-cobaltite was identified as the primary As host in a relatively small subset of samples of these lithologies (Figure 5.5-12 and Table 5.5-5).

- A single Metasediment 2 sample (17% of Metasediment 2 samples) with gersdorffite-cobaltite as the primary As host mineralogy had relatively high S and As solid phase content and was also PAG.
- Two Metasediment 3 samples with this host mineralogy represented a relatively high proportion of Metasediment 3 samples (40%) with As solid phase contents of 14 and 37 mg/kg and column leachate concentrations above the screening value for As.
- Three Fragmental 2 samples (COL-33, COL-34 and HC-35) had As mainly as gersdorffite-cobaltite or As sulphide (und.) [10]. These samples had low solid phase As content (approximately 30 to 45 mg/kg) and leachable As above the interim PWQO screening value.
- Three samples of Basalt (COL-7, COL-8 and HC-22) had As mainly as gersdorffite-cobaltite. COL-7 had solid phase As content of 46 ppm and leached As above the screening level. In comparison, samples in COL-8 and HC-22 had very low As content in the solid phase (2.3 and 4.2 mg/kg, respectively) and did not leach As above the screening level.

Based on the available information, some samples of Metasediment 3, Basalt and Fragmental 2 appear to have a greater potential for As leaching due to the presence of gersdorffite-cobaltite in low sulphide rock (Table 5.5-6). To mitigate the potential for As leaching, metal leaching thresholds were defined for As to guide rock management for the Project.

5.5.6 KEY FINDINGS

Metal Leaching Thresholds

Based on column test results, only As has been identified as a parameter of interest for metal leaching from Project rock. Leaching of As has been shown to vary distinctly based on the As sulphide mineralogy present (Section 5.5.5). Different As sulphide associations are also observed among the different lithologies (Figure 5.5-15), and leaching thresholds can be interpreted by lithology based on primary As host mineralogy. It is noted that where upper As leaching limits are indicated, they are conservative and defined by the highest As leaching samples. There are lower As leaching samples at similar or higher solid phase concentrations in each case.

Felsic Volcanics

- Arsenopyrite and Fe sulphides (pyrite / pyrrhotite) were the primary As hosts in the Felsic Volcanic samples. Samples with arsenopyrite generally also contained pyrite or pyrite and pyrrhotite and were observed to leach As at relatively low rates and below the interim PWQO screening value except where As solid phase content was elevated (>100 mg/kg). These elevated As content samples represent a small fraction of the dataset.
- Based on these results, an upper limit of 100 mg/kg As solid phase content for non-As leaching Felsic Volcanic rock was identified (Figure 5.5-15).

Metasediments and Fragmental

- Pyrite and / or arsenopyrite were the primary As hosts. Some samples of the Metasediment and Fragmental lithologies were identified to contain gersdorffite-cobaltite as the primary As hosts.
- Samples with gersdorffite-cobaltite and low contents of other sulphides, namely COL-5 (Metasediment 3), COL-6 (Metasediment 3), and COL-33 (Fragmental 2) leached relatively high concentrations of As above the interim PWQO screening value with relatively low solid phase As content of <41 mg/kg.

[10] As sulphide (und.) is defined as As sulphide undifferentiated. Additional details are provided in Section 5.3.

- Two higher As content Fragmental 2 samples (COL-31 and COL-32) at 140 and 46 mg/kg respectively leached As at concentrations at or below the below the interim PWQO screening value and had As mineralogy mainly identified as arsenopyrite.
- Based on these results a threshold of 12 mg/kg solid phase As was conservatively identified for non-As leaching Metasedimentary and Fragmental (Figure 5.5-15).

Basalt

- Detailed mineralogy for the Basalt samples identified a range of different primary As mineral hosts. Arsenic was hosted by arsenopyrite and pyrite in most samples. Arsenic was hosted by gersdorffite-cobaltite in isolated samples.
- Most basalt samples leached low levels of As despite having a wide range of solid phase As contents. Arsenic was hosted by arsenopyrite, pyrite, or an undifferentiated As sulphide in these samples. Higher As leaching was noted for Basalt COL-7 (46 mg/kg As) attributed to gersdorffite-cobaltite as the primary As host in the sample. However, other Basalt samples with low concentrations of As that contained gersdorffite-cobaltite as the main As host phase leached low levels of As.
- Based on the observed variability for Basalt, an As leaching threshold based on the highest observed enhanced As leaching sample (46 mg/kg) is proposed (Figure 5.5-15). This recognizes that As leaching is expected to decline for material below this threshold and a portion of this material will have very low As leaching. Thus, the net As leaching rates and resulting concentrations are expected to be relatively low for material below this threshold.

Summary Guidance for Mine Rock Management

Guidance for managing NPAG rock for the Project is summarized in Table 5.5-7. Non-metal leaching (NML) NPAG rock is identified as geochemically suitable for construction or placement in the NPAG non-metal leaching stockpile.

- Felsic Volcanic (Felsic Volcanic 1 and Felsic Volcanic 2) NPAG rock with As solid phase content ≤100 mg/kg can be considered NML on the basis of column leaching results and consistently identified arsenopyrite and pyrite dominant As host mineralogy in these rock types.
- NPAG Basalt rock with an As solid phase content ≤46 mg/kg can be considered NML based on the understanding of As mineralogy and leaching in this rock type.
- NPAG Metasediments (Metasediment 2 and Metasediment 3) and Fragmental (Fragmental 1 and Fragmental 2) rock types with As solid phase content ≤12 mg/kg can be considered NML based on column leaching results and identification of gersdorffite-cobaltite in these rock types.
- Low S argillite rock has been identified in low quantities within the future underground development. In the absence of characterization of this specific material for metal leaching characteristics, only rock ≤12 mg/kg As should be considered NML.
- NPAG Sericite Schist, Rhyolite and other lesser rock types (e.g., <3% of the mine volume) are considered NML based on small quantities and generally low As solid phase content observed in block models. Though expected to be a low risk for metal leaching, use in construction is not recommended since leachability testing was not completed.

The identified As thresholds have been applied to the ML / ARD block model for the Project. The projected proportions of NPAG / NML rock and overall NPAG rock volumes are shown in Table 5.5-8.

- Based on the thresholds derived from column testing, relatively high proportions of NPAG rock would be identified as NML.
- Other rock types including Sericite Schist and Rhyolite have not been assessed for metal leaching but are small in quantity and have generally low solid phase As content overall and therefore are considered NML at this time.
- Overall, low quantities of the identified NPAG rock volume are expected to be metal leaching and require management.

Table 5.5-1: Column Program Summary

Rock Type	Rock Type ID	Number of Column Tests
Felsic Volcanic 1	FV1	13
Felsic Volcanic 2	FV2	5
Metasediment 2	MS2	3
Metasediment 3	MS3	2
Fragmental 1	Frag1	-
Fragmental 2	Frag2	4
Basalt	Basalt	6
Argillite	S1A	1
Total		34

DX450077	HC-22	Basalt	Gersdorffite-Cobaltite	0.15	4.2	No
DX450113	COL-11 / HC-23	Basalt	Arsenopyrite	0.49	390	No
DX550101	COL-12 / HC-24	Basalt	Arsenopyrite	0.06	3	No
DX450128	HC-25	Basalt	As Sulphide (und.)	1.07	22	No
DX550073	COL-7	Basalt	Gersdorffite-Cobaltite	0.09	46	Yes
DX550053	COL-8	Basalt	Gersdorffite-Cobaltite	0.13	2.3	No
DX550089	COL-9	Basalt	Pyrite	0.85	2	No
31795	HC-35	Frag2	Inferred Gersdorffite-Cobaltite**	0.13	28	Yes
31759	COL-31	Frag2	Arsenopyrite	0.09	140	No
31782	COL-32	Frag2	Arsenopyrite	0.04	46	No
31623	COL-33	Frag2	Gersdorffite-Cobaltite	0.1	41	Yes
31718	COL-34	Frag2	Inferred Gersdorffite-Cobaltite**	0.13	30	Yes

Notes:

* *Leachable As refers to column or humidity cell concentration and screening value refers to the interim PWQO screening value of 0.005 mg/L.*

** *Two samples of As sulphide (und.) inferred to be gersdorffite-cobaltite based on leaching behaviour.*

Bold text identifies low S samples (≤0.2%) with slightly elevated As (>10 mg/kg) and gersdorffite-cobaltite as the primary As host that also exhibit As leaching above the screening value.

Table 5.5-7: Guidance for Management of NPAG Rock

Lithology	Guidance*
Felsic Volcanic (FV1, FV2)	If ≤100 mg/kg As - suitable for NPAG stockpile or use in construction.
Basalt	If ≤46 mg/kg As - suitable for NPAG stockpile or use in construction.
Metasediment (MS2 & MS3)	If ≤12 mg/kg As - suitable for NPAG stockpile or use in construction.
Fragmental (Frag1, Frag2)	If ≤12 mg/kg As - suitable for NPAG stockpile or use in construction.
Argillite	If ≤12 mg/kg As - suitable for NPAG stockpile or use in construction.
Other (e.g., Sericite Schist and Rhyolite)	Suitable for NPAG stockpile. Not suitable for construction.

Notes:

* *For mine rock management, solid phase As content is based on four acid digest results for consistency with the exploration data and block model results.*

Table 5.5-8: Lithology Proportions Based on As Thresholds

Rock type	Rock type ID	LP Central Pit [1]					Underground [1]				
		Proportion of Total Pit Volume	Prportion of Lithology		NPAG Rock [4]		Proportion of Underground Volume	Prportion of Lithology		NPAG Rock [4]

Notes:

1 Classification as mine rock or ore-grade materials was based on whether samples contained an economic gold content for the LP Central Pit. Classification as mine rock provided by Great Bear Resources for the underground. Proportions were calculated from Project ML / ARD block model.

2 Basalt includes several basalt types including Foliated Mafic Flow, Pillow Basalt, Massive Basalt, and Biotite Calcite Pillow Basalt.

3 Other low abundance lithologies including Ultramafic, Rhyolite, Sericite Schist, Amphibole Schist and Dyke 1.

4 Percentage of NPAG rock as metal leaching or non-metal leaching is relative to total mine volume.

5 Indicates no volume of rock type is present in the block model.

6 Indicates volume of rock type present in the block model, but no PAG or metal leaching proportions were identified.

7 Indicates volume of rock type present in the block model, but only PAG proportions were identified.

Orange cells represent lithology proportions where ≤100 mg/kg As is non-metal leaching.

Green cells represent lithology proportions where ≤46mg/kg As is non-metal leaching.

Blue cells represent lithology proportions where ≤12 mg/kg As is non-metal leaching.

Yellow cells represent lithology proportions assumed to be non-metal leaching based on generally low As content in block models.

5.6 FIELD LEACH BARREL TESTING

5.6.1 OVERVIEW

Field kinetic testing using Field Leach Barrel (FLB) tests was conducted as part of the ML / ARD assessment. A total of 16 FLB tests were constructed at the Great Bear site in July 2023 (Table 5.6-1). The FLB tests contain samples representing Project rock types.

Each test was prepared using approximately 100 to 200 kg of drill core, representing key lithologies with varying S and metal contents. The drill core was carefully placed into an open-top 250 L drums equipped with a quartz sand filter bed and connected to a sealed sampling vessel through a basal drain and pipe. Precipitation can contact the drill core, and the resulting drainage is collected in the sampling vessel.

Leachate chemistry from these tests has been routinely monitored to evaluate field-scale acid generation potential and metal release. Approximately 1.5 years of monitoring data is available. This includes data up to the end of the 2024 monitoring season (October 2024) as summarized in this section.

Routine monitoring of the tests is ongoing.

5.6.2 SUMMARY OF FLB TESTS

A summary of the FLB test program is provided below. There are a total of 16 tests currently in operation, including 15 FLBs containing drill core and one FLB blank containing only the filter media (quartz sand) used in the tests. The sample height and mass contained in each barrel is summarized in Table 5.6-2. Geochemical descriptions of the test samples are provided in Table 5.6-3. Detailed information on FLB set up, sampling and geochemical testing is provided in Section 4.5.1.

The FLB tests were constructed on the Project site by WSP during June and July 2023 and are located adjacent to the Great Bear weather station. Drill core samples in the FLB tests were selected from recently drilled core representing the proposed mine volume, including the currently planned open pits and underground workings. Sample selection was based on review of drill core logs plus the results of continuous multi-element ICP data. Each FLB was selected to represent a single lithology, with a focus on key lithologies for the Project. Drill core representing a range of As and other metal contents was selected for use in the tests.

Prior to placement in the FLBs, all drill core intervals selected for testing were inspected by qualified WSP personnel. Representative subsamples (10 to 14 per barrel) were collected for ML / ARD verification testing to confirm the geochemical properties of each test sample (Appendix F, Table F-1).

- Table 5.6-3 provides a summary of the ML / ARD characteristics of the FLB tests, based on the above subsamples. The data presented represents a weighted average of the data based on the interval lengths used.
  - For all elements other than As, the elemental content data shown for each FLB is based on aqua regia digest results for the subsamples. Percentile ranks are relative to the aqua regia ICP-MS database (n=3,885 samples).
  - For As specifically, four acid digest results were used to represent the As content of the samples. Four acid ICP-MS data were used for As as this data is the basis for the Project As leaching thresholds (Section 5.5). Percentile ranks for As are relative to the four acid database (n=3,882 samples).
- ABA and elemental content results are detailed in Tables F-2, F-3 and F-4 in Appendix F, respectively.

Samples selected for FLB testing were chosen to represent a broad range of geochemical characteristics of Project rock. As shown in Table 5.6-4 tests were constructed that represented all key Project lithologies and included a range of NP contents, S contents and metal contents.

ABA and elemental content data for the subsamples are shown relative to data from the ML / ARD dataset and the Project block model in Figure 5.6-3 to Figure 5.6-17. The subsamples showed reasonably consistent characteristics for most of the FLBs (Figure 5.6-3 to Figure 5.6-17). Elemental content data for the subsamples was also generally consistent with the exploration ICP data for the drill core used in the tests.

Leachate chemistry was monitored through bi-weekly sampling and testing by Great Bear Resources. The following section presents the available test results of the FLB testing. This includes approximately 20 leachate sampling events, covering the time period from July 2023 to October 2024.

5.6.3 LEACHATE SAMPLING AND ANALYSIS

Leachate sampling was conducted by Great Bear Resources personnel. Sampling occurred bi-weekly from July to October 2023 and April to October 2024, totaling 20 sampling events (Table 5.6-5; Appendix F, Table F-5). Leachates were collected during spring to fall conditions in 2023 and 2024, but not during periods of ice buildup or when insufficient water was available due to dry weather.

Leachates were analyzed at ALS in Winnipeg, Manitoba. Detailed methodology is provided in Section 4 of this report.

Precipitation data collected from the site's weather station were monitored and compared to the leachate volumes recovered from the tests to validate the performance of the FLBs. All FLB tests functioned properly, with no leaks observed or adjustments required during the monitoring period.

Table 5.6-6 provides a summary of the analyses performed on the FLB leachate and field blank samples, including field parameters, dissolved metals, Hg, and other constituents such as anions and total phosphorus.

5.6.4 SCREENING APPROACH

- Leachate results were compared to screening values as applicable to provide context to the observed results. It is recognized, however, that the tests are not a direct assessment of mine water quality and comparisons to screening criteria hold no regulatory significance.
- The screening analysis included a comparison of the leachate chemistry to water quality objectives for the protection of aquatic life, including both PWQO values and interim PWQO values.
- Leachate chemistries were analyzed to calculate release rates and identify trends in metal release. The metal release rates were determined based on the mass of drill core used in each FLB test, representing median release rates over the monitoring period.

5.6.5 QUALITY ASSURANCE AND QUALITY CONTROL

FLB data were reviewed for QA / QC purposes on an ongoing basis during as outlined below. Field blank (FLB-B) data and duplicate results are provided in Appendix F. Detection limits and methods are summarized in Appendix A. Certificates of analysis are provided in Appendix O. QA / QC evaluation included:

- Assessment of laboratory QA / QC reports of internal blank measurements, hold time evaluations, and internal duplicate measurements.
- Collection and assessment of field blank samples (deionized water decanted into sample bottles at the field site) and field duplicate samples (two leachate samples collected from the same barrel where one sample was submitted as a blind duplicate).

- Collection and assessment of leachate from the blank FLB test (FLB-B; quartz sand filter media) to measure background conditions.

Overall, assessment of QA / QC data indicated good data quality for the FLB leachates. Results of QA / QC analyses included the following observations:

- Laboratory QA / QC reports indicated that laboratory blanks met ALS data quality objectives for all reports received, with rare exceptions (four out of approximately 1,000 measurements).
- Field blank metal concentrations were typically non-detectable. In some cases, field blank measurements were marginally greater than the analytical detection limit. Rarely, field blank measurements indicated high background levels of some parameters, including measurements of Ca, Mg, K and Sr during one sampling event in September 2024. Phosphorous in the field blank was also commonly detected and followed the same pattern of fluctuating concentrations as other FLBs, suggesting the presence of organic matter (leaves) in the barrels. Elevated background concentrations in the field blank did not appear to affect results for other FLB tests.
- Hold times were within the recommended guidelines with the exception of laboratory pH measurements which have a hold time of 15 minutes and are not practical to assess within that timeframe for field samples. To account for this known short hold time, field pH measurements were collected for each FLB at every sampling event. All leachates dispensed into bottles pre-loaded with preservatives for select analytes as required by the laboratory and were stored in refrigerated conditions (stored in a refrigerator or transported in coolers).
- Duplicate analyses completed by the laboratory were generally acceptable, as outlined in the certificates of analysis.
- Field duplicates indicated good replicability, with sample results that were generally within ±10% for concentrations that were greater than five times the analytical detection limit. In rare instances (i.e., individual parameter measurements), larger relative percentage differences were observed; however, the absolute difference between the sample concentrations was typically small.
- Leachate chemistry from FLB-B indicated that leachate concentrations of metals in this barrel were low relative to FLB tests containing drill core and below the analytical detection limit for most parameters. Leachate pH in this barrel was circumneutral.

5.6.6 RESULTS

The results of the field parameters and laboratory analyses of the FLB leachate samples are presented and discussed in the following subsections. Concentration trends for all currently monitored parameters are illustrated in Appendix F. Available leachate results including those for QA / QC samples are also provided in Appendix F.

pH and Temperature

Key observations for measured field parameters are summarized below. The leachate pH and temperature were measured on the Project site during leachate collection, with leachate pH also measured in the laboratory.

- Laboratory leachate pH (lab pH) measurements (Figure F3-1 of Appendix F3) in the FLBs showed more consistency between sampling events and were generally on the order of pH 7 to 8 for most tests and were relatively consistent with those obtained from humidity cell tests.
- The field-measured leachate pH (field pH) of the FLB leachates ranged from circumneutral to alkaline, typically between 6.5 and 8.5 (Figure F3-2). Occasional measurements of pH slightly outside the bounds of PWQO screening values (6.5-8.5) were observed. This primarily occurred for samples of Felsic Volcanic and Metasedimentary rock.
- Laboratory pH for FLB-07 (Felsic Volcanic 1, High S, Very Low NP, PAG) has been gradually decreasing. Laboratory measurements indicate mildly acidic conditions, with pH consistently below 6.5 during September and October 2024, and a current reading of 6.2. Leachate for FLB-13

(Metasediment 2, Typical S, Very Low NP, PAG) also shows a decreasing trend in pH, with pH on the order of 6.5 in recent data.

- Temperatures recorded at the time of sample collection generally align with seasonal ambient conditions (Figure F3-3), ranging from 1.0 °C in early spring to 30.2 °C during the summer.

Acidity, Alkalinity and Sulphate

- Acidity levels were typically at or near the analytical detection limit (2 mg $CaCO_3$/L) for the majority of the test period (Figure F3-7). Erratic acidity trends were observed between August through October 2024. In particular, FLB-03 (typical S, typical NP, Uncertain, Felsic Volcanic 1) and FLB-05 (high S, typical to low NP, PAG, Felsic Volcanic 1) showed slight increases, with acidity concentrations of 55 mg $CaCO_3$/L and 7.2 mg $CaCO_3$/L in August 2024, respectively. Recent acidity increases were observed for FLB-03, FLB-04 and FLB-12.
- Alkalinity concentrations ranged from 2.6 to 107 mg $CaCO_3$/L, with a median value of 29 mg $CaCO_3$/L (Figure F3-8). Sample FLB-03 (typical S, typical NP, Uncertain, Felsic Volcanic 1) exhibited elevated alkalinity in August 2024 (75 mg $CaCO_3$/L), consistent with trends in acidity and conductivity observed during the same period. Relatively low and / or declining alkalinity concentrations were seen primarily in Metasediments and one Felsic Volcanic test. FLB-07 (Felsic Volcanic 1, high S, low NP, PAG) and FLB-13 (Metasediment 2, Typical S, Very Low NP, PAG) had declining alkalinity concentrations in recent data, consistent with observed pH trends for these tests.
- Sulphate concentrations across samples ranged from 1.0 to 80 mg/L, with a median concentration of 13.8 mg/L. Sulphate exhibited a seasonal trend, with higher concentrations observed during the fall and lower concentrations in spring.
  - Basalt samples (FLB-8, FLB-9 and FLB-10) consistently displayed sulphate concentrations at or below 10 mg/L throughout the monitoring period. Low sulphate release is consistent with their low S content and elevated NPR and CarbNPR, indicating substantial NP and pH buffering capacity.
  - Felsic Volcanic 1 (FV1) samples, particularly FLB-05 and FLB-07, showed some of the highest sulphate release rates compared to the other FLB tests. This is consistent with their high S content and lower NPRs. FLB-07, with a total S content of 4.1%, exhibited sulphate concentrations ranging from 15 to 53 mg/L.
  - Metasediment 2 (MS2) samples FLB-13 and FLB-14 exhibited elevated sulphate concentrations relative to other FLBs, showing trends comparable to the Felsic Volcanic 1 samples. Notably, FLB-13 (typical S, PAG) reported sulphate levels as high as 80 mg/L.
  - Recent data indicate sulphate concentrations below 40 mg/L in all samples except for PAG samples FLB-07, FLB-13 and FLB-14, which reported concentrations between 45 and 80 mg/L.

Leachate Metal Concentrations

The concentrations of key metals in FLB leachates are discussed below.

FLB tests with a higher solid phase As content generally showed higher As release, consistent with observations in other kinetic tests for the Project.

- Several tests had As concentrations in leachates that were consistently greater than the interim PWQO screening value (0.005 mg/L) including Felsic Volcanic 1 samples FLB-01, FLB-04, FLB-06 and FLB-08 (Basalt). FLB-12 (Felsic Volcanic 2) was consistently equal to or greater than or at the PWQO screening value (0.1 mg/L). These tests had neutral leachates and were classified as PAG materials with an elevated solid phase As content (on the order of 120 to 1,600 mg/kg, representing the 93rd to 99th percentile of the ML / ARD dataset). One Felsic Volcanic 1 FLB (FLB-03) with relatively low As content (14 mg/kg) had leachate concentrations slightly greater than the interim PWQO screening value in recent data despite low As concentrations for most of the preceding monitoring period.

- Other PAG FLBs (Felsic Volcanic and Metasedimentary rock types) had leachate concentrations below the interim PWQO screening value even when solid phase As contents were elevated (up to 348 mg/kg; 88th percentile).
- Four FLBs were NPAG including two Felsic Volcanic FLBs (FLB-02 and FLB-11) and two Basalt FLBs (FLB-09 and FLB-10). The results from these tests were inspected with respect to the As leaching thresholds established (Section 5.5 Columns) for Felsic Volcanic (100 mg/kg) and Basalt (46 mg/kg).
  - The Felsic Volcanic tests both had a low solid phase As content (e.g., approximately 5 to 15 mg/kg). Arsenic concentrations in the leachates from FLB-02 were approximately an order of magnitude lower than the interim PWQO screening value. FLB-11 had As concentrations at or slightly above the interim PWQO screening value. FLB-11 had an As content of approximately 13 mg/kg and a S content of 0.14%. Similar materials have shown As leaching at relatively low As contents in other kinetic tests, likely due to the presence of low levels of the As sulphide mineral gersdorffite-cobaltite.
  - The tests containing Basalt had As contents of 63 mg/kg (FLB-09) and 23 mg/kg (FLB-10). FLB-09 had average As contents greater than the established As threshold value for Basalt (46 mg/kg). Arsenic concentrations in leachates were relatively steady and averaged at or slightly below the interim PWQO for As during the monitoring period (median leachate concentration 0.004 mg/L). FLB-10 had a relatively low As content (23 mg/kg) with a median leachate concentration of 0.003 mg/L. Leachate concentrations in FLB-10 varied and several events had As concentrations higher than screening values. This was attributed to the presence of isolated pieces of core in FLB-10 that may contain gersdorffite-cobaltite based on As:S information for the core, which may be influencing As release from the test. Such samples are understood to be non-representative of the bulk of the NPAG Basalt.
  - The existing As thresholds developed from laboratory kinetic test data remain valid and should continue to be utilized. It is noted that these NPAG tests were initiated prior to the development of current As thresholds, and before information on site-specific As host mineralogy was available.

Trends for other metals are described below:

- Cadmium concentrations were steady in the first two years of operation for most FLBs, and most barrels had concentrations below the interim PWQO value (0.0001 mg/L). A few FLBs (FLB-05, FLB-07 and FLB-13) containing Felsic Volcanic 2 and Metasediment 2 samples had Cd concentrations above the interim PWQO value (0.0002 mg/L) and / or the PWQO value (0.0001 mg/L).Higher Cd concentrations in FLB leachates generally correlated with higher solid phase Cd content (FLB-05 and FLB-07) or declining leachate pH (FLB-13).
- Cobalt concentrations remained stable in 2023 and 2024 for most cells. Elevated and somewhat erratic trends were observed for three FLBs comprising Metasediment 2 (FLB-13 and FLB-14) and Felsic Volcanic 1 (FLB-07). Elevated Co concentrations (up to 0.01 mg/L) were consistent with the observed declining pH trend in these tests.
- Copper concentrations in the samples ranged from near the detection limit (0.0002 mg/L) to 0.007 mg/L, with a median value of 0.0015 mg/L. Concentrations were similar among FLB tests of all lithologies, and most measurements were below the interim PWQO value (0.005 mg/L). Isolated measurements of Cu in some Felsic Volcanic leachates were above the interim PWQO value, with concentrations up to approximately 0.01 mg/L observed.
- Concentrations of Hg below the analytical detection limit (0.0000005 mg/L) were reported for all FLB leachates throughout the monitoring period.
- Most FLB tests had Ni concentrations that were below the PWQO value (0.025 mg/L) and concentrations were typically near to or below the analytical detection limit (0.005 mg/L). Nickel concentrations were notably elevated in leachates for PAG samples FLB-07 (Felsic Volcanic 1) FLB-13 (Metasediment 2) and FLB-14 (Metasediment 2), with FLB-13 reaching a peak of 0.1 mg/L. Elevated Ni concentrations generally correlated with higher nickel content.

- Lead concentrations were consistently low, remaining below the interim PWQO (0.001 mg/L) value across all FLBs.
- Selenium concentrations were steady and consistently below the PWQO screening value throughout testing. A positive relationship was observed between solid-phase Se content and leachate concentrations, with Basalt samples (FLB-08, FLB-09 and FLB-10) displaying the lowest Se concentrations.
- Most FLBs had Zn concentrations below the PWQO value (0.03 mg/L) and interim PWQO value (0.02 mg/L) for the duration of 2024. FLB-05 (Felsic Volcanic 1) exhibited the highest Zn concentration, attributed to its materially elevated solid-phase Zn content (0.6%, 99th percentile among the ML / ARD dataset).

5.6.7 KEY FINDINGS

Release Rates

Median release rates over the monitoring period are summarized in Table 5.6-7. Figures showing the release rates calculated for each sampling event are provided for all parameters in Appendix F3.

Release rates were calculated as follows:

- The total load released from the FLB tests between initiation in July 2023 and October 2024 was considered in determination of the release rates for each test.
- It was assumed that no load was released during the winter months. During this time, no liquid water was released from the tests due to freezing conditions.
- Release rates were normalized to the mass of rock in each test. Release rates are expressed per unit time to represent the active (non-frozen) periods of testing for comparison to humidity cell test results.

The release rates observed during the FLB tests predominantly reflect circumneutral pH conditions, with median pH values ranging from 7.0 to 7.8. As previously described, two PAG tests with a low NP contents, FLB-07 (Felsic Volcanic 1) and FLB-13 (Metasediment 2), showed slightly decreasing trends in pH and had pH on the order of 6.2 to 6.5 in recent data.

Comparison of Field and Laboratory Sulphate Release Rates

A comparative analysis of sulphate release in the FLB and humidity cell tests was conducted to evaluate sulphide oxidation rate differences between field and laboratory conditions (Figure 5.6-2). The following key observations were noted:

- Median sulphate concentrations from FLB testing were on the order of five to ten times higher than median sulphate concentrations from humidity cell testing. This is primarily attributed to the higher degree of flushing in humidity cell tests compared to the FLBs (i.e., higher water to rock ratio), which receive only local precipitation. To account for these differences, a mass-normalized rate was calculated for the FLBs using the total mass of rock in the test and compared to mass-normalized rates from humidity cell testing.
- Sulphate release rates and S content trends observed in humidity cell tests were also observed in FLB tests, whereby samples with lower solid phase S contents had lower sulphate release rates than samples with a higher solid phase S content.
- Median sulphate release rates for each lithology from the FLB tests were typically lower than the laboratory humidity cell tests. Median sulphate release rates from the humidity cell tests were on the order of five times higher for samples with lower total S contents. At higher S contents, the difference in median release rates increased; release rates were approximately 10 times higher in the humidity cell tests compared to FLB tests with similar S content. The lower rates observed in the FLB tests were attributed to differences in field and laboratory conditions (e.g., temperature, flushing), as well as the higher surface area to mass ratio of samples in the humidity cell tests (drill core crushed to <6.4 mm) relative to the FLBs (pieces of drill core).

Acid Generation Potential

The FLB tests indicate that most samples exhibit circumneutral to alkaline drainage pH conditions, with seasonal pH variations influenced by ambient temperature changes. Some PAG samples including FLB-07 and FLB-13, characterized by typical to high sulphide content and low CarbNP, are showed a gradual pH decline with slightly acidic pH in recent monitoring data, signaling the potential onset of net-acid generation in these tests.

Comparison to laboratory humidity cell rates suggests that field oxidation rates for sulphides in the FLB tests range from 5 to 10 times slower than laboratory humidity cell rates, attributed to differences in flushing, temperature, and sample grain size. Current estimates of net acid generation lag times for PAG rock materials are based on laboratory derived sulphide oxidation rates. The FLB derived rates suggest that lag times could be longer under field conditions than currently estimated. However, net acid generating conditions may still occur within a limited timeframe for materials that have a very low NP content, as progression toward net acidification appears to be occurring for two tests after one year of field monitoring. Therefore, additional consideration is required when using the observed field rates to adjust laboratory-derived lag times.

Arsenic Release

Release rates for As were lower for some of the FLBs relative to the laboratory kinetic tests with a similar As content, particularly for samples with a lower solid phase As content. This may be due to reduced reactivity under field conditions or perhaps variability in As host mineralogy which has been observed to show a range of As leaching rates for samples with a similar As content. Otherwise, trends in As release for the FLBs were generally consistent with the laboratory kinetic tests, whereby samples with a higher As content generally had higher As release rates than samples with a lower As content.

At present there are four FLBs in operation with NPAG materials, including two FLBs containing Felsic Volcanic and two FLBs containing Basalt. The results from these tests were inspected with respect to the As leaching thresholds established for Felsic Volcanic (100 mg/kg) and Basalt (46 mg/kg).

Currently available data for these tests is relatively consistent with laboratory test data, however, some of the NPAG materials in the FLBs may contain As sulphide minerals that may not be highly representative of the overall NPAG rock for the Project. In particular, the two NPAG tests FLB-11 (Felsic Volcanic) and FLB-10 (Basalt) have As and S levels that are similar to samples that have been observed to contain the As sulphide mineral gersdorffite-cobaltite. While this phase is understood to not be pervasive among the Project rock, elevated As leaching at low solid phase As contents has been observed to occur where it is present. Therefore, it is possible that As release rates from these barrels are overestimating As release relative to how more typical NPAG material will perform.

These tests were initiated prior to the development of the current As leaching thresholds and before information on site-specific As host mineralogy was available. The current As leaching thresholds for NPAG rock remain valid.

Other Metals

Metal release from the FLBs was evaluated for other metals. Concentrations in FLB leachates for other metals including Pb, Cr, Ag and Hg were below analytical detection limits and screening values for all tests. Concentrations of Sb, Mo, Se, W and V were below screening values for all tests.

Concentrations of Cd, Co and Ni were below screening values in all NPAG test leachates. Concentrations of Cu were below screening values in all NPAG test leachates aside from one sampling event for FLB-11 where Cu was marginally above the screening value; all other leachates for this test had low Cu concentrations.

Concentrations of Cd, Co, Ni, Cu, U and Zn were greater than screening values in several Felsic Volcanic and / or Metasediment tests that were PAG. Generally, these tests had higher sulphur and solid phase metal contents or declining leachate pH (FLB-07, FLB-13). These samples are not representative of the bulk of the Project rock. Leachates for some of the Felsic Volcanic tests had U concentrations that were higher than screening values on isolated occasions; however, U concentrations were generally below screening values for these tests.

Table 5.6-1: FLB Program Summary

Rock type	Rock type ID	Number of FLB tests [1]
Felsic Volcanic 1	FV1	7
Felsic Volcanic 2	FV2	2
Metasediment 2	MS2	2
Metasediment 3	MS3	1
Basalt	Basalt	3
Total		15

Notes:

1 In addition to the FLB tests constructed with rock, one blank barrel consisting of only the filter media (quartz sand) was constructed as an experimental control.

Table 5.6-2: Summary of Drill Core Added to FLB Tests

FLB ID	Lithology	Height of Rock in Barrel (m)	Mass of Rock in Barrel (kg)
FLB-01	FV1	0.49	217
FLB-02	FV1	0.43	191
FLB-03	FV1	0.40	177
FLB-04	FV1	0.31	138
FLB-05	FV1	0.38	169
FLB-06	FV1	0.32	142
FLB-07	FV1	0.34	149
FLB-08	Basalt	0.30	131
FLB-09	Basalt	0.32	142
FLB-10	Basalt	0.34	151
FLB-11	FV2	0.24	106
FLB-12	FV2	0.28	124

FLB-14	MS2	0.34	151
FLB-15	MS3	0.31	138

Table 5.6-3: Summary of ML / Acid Generation Potential of the FLB Tests

FLB ID	Acronym	Acid Rock Drainage Potential (1)	Key Metals Description		
			Elevated Concentrations (>75th percentile)	Typical Concentrations (40th to 75th percentile)	Low Concentrations (<40th percentile)
FLB-01	FV1	Uncertain	As (97th percentile)	Pb, Cd, Se, Zn	Ni, Cu, Co
FLB-02	FV1	NPAG	Ni (81st percentile)	Co, Cd, Cu, Zn	Se, As, Pb
FLB-03	FV1	Typical S, Uncertain	Ni (87th percentile)	Co, Cd, Pb, Zn, Se, As, Cu	--
FLB-04	FV1	Typical S, Uncertain	As (99th percentile) Ni, Se (83rd to 84th percentile)	Co, Cu, Pb, Cd	Zn
FLB-05	FV1	High S, PAG	As (76th percentile) Pb, Zn, Cd, Cu, Se (98 to 99th percentile)	Ni, Co	--
FLB-06	FV1	Typical S, PAG	As (93rd percentile) Cu, Pb, Ni, Zn (82nd to 85th percentile) Se (79th percentile)	Co, Cd	--
FLB-07	FV1	High S, Very Low NP, PAG	Se, Ni, Co (91st percentile) As (83rd percentile)	Pb, Cd, Zn	Cu
FLB-08	Basalt	High S, Uncertain	As (93rd percentile) Cd, Zn (90 to 95th percentile) Pb, Se (88th percentile)	Ni, Co	Cu
FLB-09	Basalt	Typical S, NPAG	As (85th percentile) Co (84th percentile)	Ni, Cu, Zn, Cd, Pb, Se	--
FLB-10	Basalt	NPAG	--	As, Cu, Co, Pb, Ni, Cd, Zn	Se
FLB-11	FV2	NPAG	Ni (87th percentile) Co, Cu (80 to 86th percentile)	Zn	Cd, Se, As, Pb
FLB-12	FV2	Typical S, PAG	As (96th percentile) Pb, Se (82nd to 89th percentile) Cd, Ni, Zn (76th to 78th percentile)	Co, Cu	--
FLB-13	MS2	Typical S, Very Low NP, PAG	As (88th percentile)	Pb, Se, Ni, Cd, Cu, Co	Zn
FLB-14	MS2	Typical S, PAG	Pb, Se (91st percentile) Zn, Cd, Cu (82nd to 86th percentile)	As, Ni	Co
FLB-15	MS3	High S, PAG	Se, Pb (80th percentile)	Cd, Cu, As, Co, Ni, Zn	--

Notes:

1 *Acid generation potential and elemental content characteristics are based on results for all subsamples (n=10 to 14).*

2 *Statistical descriptions are relative to the specific lithology in the ML / ARD database for all tests. If not specified directly, elevated refers to greater than the 75th percentile rank, typical refers to between the 40th and 75th percentile rank, and low refers to lower than the 40th percentile rank among the dataset for the lithology. Further details provided for specific elements in the table.*

3 *Percentile ranks for all parameters except As were calculated using aqua regia ICP-MS results for barrel subsamples relative to the Project aqua regia ICP-MS database (n=3,885 samples). As percentile ranks were calculated relative to the Project four acid ICP-MS database (n=3,882 samples) using four acid ICP-MS data for the barrel subsamples as Project As leaching thresholds are based on four acid ICP-MS results (Section 5.5).*

Notes:

1 Total S measured by Leco furnace. Sulphate S measured by HCl leach. Sulphide S calculated by difference (Total S – Sulphate S = Sulphide S).

*2 Calculated as 31.25*Sulphide S by difference.*

*3 Calculated as 31.25*Total S by Leco furnace.*

4 Measured by HCl leach and Leco furnace.

*5 Calculated from TIC (TIC*10*(100/12.01) = CarbNP).*

6 MEND 1991 method, based on the 1989 Lawrence Modified NP method.

7 NPR calculated as the ratio of the weighted average NP to the weighted average AP. CarbNPR calculated as the ratio of the weighted average CarbNP to the weighted average MPA.

Table 5.6-5: 2023 to 2024 FLB Sampling Schedule

Month	Number of Weeks of Test Operation	Sampling Dates	Samples Collected
July	3	July 27, 2023	FLB-01, FLB-02, FLB-03, FLB-04, FLB-05, FLB-06, FLB-07, FLB-08, FLB-09, FLB-10, FLB-11, FLB-12, FLB-13, FLB-14, and FLB-15 Duplicate FLB Sample [1] Blank FLB (FLB-B) Field blank (FB; lab-supplied deionized water)
August	6	August 16, 2023	
	8	August 27, 2023	
September	10	September 11, 2023	
	12	September 27, 2023	
October	14	October 9, 2023	
	15	October 20, 2023	
April	41	April 13, 2024

6 TAILINGS

6.1 SUMMARY

Static testing and kinetic testing were conducted on synthetic tailings samples produced as part of metallurgical testing for the Project, including desulphurized tailings and concentrate tailings. Static testing and kinetic testing were also conducted on samples representing whole tailings that will be used to generate paste backfill, as well as samples of prepared paste backfill. The ML / ARD characteristics of these materials are summarized below and described in greater detail through Section 6.

Desulphurized Tailings

Desulphurized tailings samples are NPAG with a low total S content (median 0.18%), primarily present as sulphides (pyrite). Desulphurized tailings had no potential for net acidic leachates and low metal release rates based on humidity cell testing. Mercury concentrations in test leachates were below or at the analytical detection limit throughout testing. Solid phase metal concentrations were low and were usually below screening values.

Analyses conducted on supernatant samples (post-cyanide destruction; post-CND) representing process water to be discharged with the tailings indicated that the process water generally had a circumneutral pH with generally low metal concentrations. Metal concentrations were below qualitative screening values for most elements with the exception of P and Co (all samples) and As, Cu, Fe, Mo and Sb in isolated samples. Sulphate concentrations were on the order of 1,000 mg/L and were attributed to the addition of sulphate as a reagent during the CND process.

Concentrate Tailings

Concentrate tailings samples are PAG. The samples had an elevated total S content (median 32%), present as sulphides (mainly pyrite). Consistent with their high sulphide content, the samples had elevated solid phase concentrations of several metals (Ag, As, Cd, Cu, Se, Pb, Mo, Zn, Sb and W).

Results of the subaqueous recirculating column test on the concentrate tailings sample indicated that oxidation of the material was limited under submerged conditions as are proposed for the Project. Consistent with low rates of sulphide oxidation, metal release rates for the concentrate tailings sample were low and many parameters (including Sb, Be, Cr, Pb, Mo, Ni, Ag, Tl, W, V, Zn and Zr) were below analytical detection limits.

Analyses conducted on supernatant samples (post-CND) representing process water to be discharged with the concentrate tailings indicated that supernatant had circumneutral pH and sulphate concentrations of approximately 1,000 mg/L, which is attributed to the addition of sulphate in the CND process. Most elements in the concentrate supernatant were below qualitative screening values with the exception of P and Co (all samples) and several other elements (As, Cu, Fe, Mo, Cd, Cr, Sb and Pb) in isolated samples. Concentrations of P were attributed to the reagents used during flotation. Mercury was below screening values and the analytical detection limit.

Whole Tailings

Whole tailings (e.g., tailings generated that have not undergone flotation) will be used to generate paste backfill. The whole tailings samples representative of the LP Zone were PAG with median total S content of 1.2%. Sulphur was mainly present as pyrite in the samples, although some samples contained pyrite and pyrrhotite.

Humidity cell testing indicated that metal release rates from the whole tailings samples were generally low under current neutral leaching conditions. Based on the humidity cell test results, lag times were estimated to be on the order of 10 years for whole tailings that represent the life of mine LP tailings to be used for backfill generation.

Paste Backfill

Paste backfill was prepared from whole tailings samples representing the life of mine whole tailings. Properties of the paste backfill sample were similar to the whole tailings from which the paste was prepared. The paste backfill sample had a total S content of approximately 1% (present as pyrite) and was classified as PAG by ABA.

Subaerial and subaqueous kinetic testing conducted on paste backfill samples generally indicated low metal release rates. Release rates from the subaqueous kinetic test, representing submerged backfill under closure conditions, were generally lower than release rates observed from the subaerial test.

Based on trends in release rates for the whole tailings and the NP and AP content of the paste backfill, a lag time to net acidic conditions for the paste backfill is currently estimated to be on the order of 10 years under laboratory conditions. However, placement of the paste backfill underground in sealed stopes will limit its interaction with oxygen and water which is expected to prolong the laboratory estimated lag time.

6.2 STATIC TESTING

6.2.1 OVERVIEW

A static testing program was undertaken to assess the metal leaching and acid generation potential of Project tailings. The program utilized synthetic tailings samples produced as part of metallurgical test work undertaken for the Project. A flotation process was used to prepare desulphurized tailings from whole tailings; the sulphides and other minerals removed from the whole tailings during this process were prepared into concentrate tailings.

Tailings samples evaluated as part of this assessment included seven samples of desulphurized tailings and nine samples of concentrate tailings. All samples underwent bench scale CND. Supernatant samples were also collected throughout various stages of the metallurgical testing to provide information regarding the process water quality that could be discharged with the tailings during operations. These samples represent the current mine plan and Project flowsheet. The results of static testing will be used to inform tailings and related water quality management strategies.

In addition to the desulphurized tailings and concentrate tailings samples, whole tailings (e.g., tailings that did not undergo flotation) were also tested. This included the assessment of nine samples of synthetic whole tailings produced in earlier metallurgical testing programs. These samples do not reflect the expected composition and geochemical characteristics of Project tailings to be discharged to surface management facilities based on the current mine plan. However, whole tailings will be used to generate paste backfill for use in the underground mine. As such, geochemical test results for the whole tailings samples are included herein for completeness.

Paste backfill is planned to be the primary form of structural backfill in the underground mine. Paste backfill was produced from synthetic whole tailings samples, Terraflow binder and water according to Project engineering specifications available at the time of sample preparation. The prepared paste backfill was included in the geochemical testing program to characterize this material. The paste backfill samples discussed below will be supplemented with additional samples prepared using whole tailings and membrane reject solution, consistent with recent updates in Project planning.

6.2.2 SUMMARY OF AVAILABLE SAMPLES

The static testing program utilized synthetic tailings samples produced as part of metallurgical test work for the Project.

The static testing program was initiated in 2022. Since that time, the Project flowsheet has progressed to optimize gold recovery and support tailings management strategies. This is common during the mine design process, and the samples tested reflect the flowsheet at various stages of Project development.

Currently, the Project flowsheet includes the following processing stages:

- Grinding, gravity separation, and cyanide leaching to recover gold.
- CND conducted on whole tailings with SO_2/air.
- Flotation to generate NPAG desulphurized tailings and a smaller volume of PAG concentrate tailings.
- The CND process is currently being optimized as part of ongoing mine engineering. This may affect the types and / or quantities of reagents used.

A summary of the synthetic tailings samples included in the static testing program is provided in Table 6.2-1 and presented in Figure 6.2-1. The samples tested were produced from three metallurgical programs that took place at SGS Lakefield from 2022 to 2024.

Desulphurized Tailings and Concentrate Tailings

Sixteen tailings samples were produced in 2024 from flotation testing that reflects the current Project flowsheet. These samples were generated from LP Zone ore composites, which are expected to comprise over 95% of the ore resources at the Project (Pfeiffer et al. 2023). Samples included the following:

- Seven samples of desulphurized tailings produced from ore composites representative of the LP Zone. Prior to geochemical testing, samples were stored as slurry in sealed and refrigerated pails.
- Nine samples of concentrate tailings produced from ore composites representative of the LP Zone. Prior to geochemical testing, samples were stored as frozen filter cakes in sealed plastic bags.

All of these samples were subjected to CND prior to flotation.

Tailings process water was also collected and included:

- Six samples of whole tailings supernatant prior to CND and prior to flotation (pre-CND and pre-flotation).
- Six samples of post-CND supernatant from the desulphurized tailings (post-CND and post-flotation).
- Six samples of post-CND supernatant from the concentrate tailings (post-CND and post-flotation).

Whole Tailings

During earlier metallurgical programs in 2022 and 2023, samples of whole tailings were produced. Samples were produced from nine ore composites, including six ore composites from the LP Zone, two ore composites from the Hinge Zone, and one ore composite from the Limb Zone. These samples included:

- Nine samples of whole tailings (not subjected to CND), including six samples of LP Zone whole tailings, two samples of Hinge Zone whole tailings and one sample of Limb Zone whole tailings. Following preparation of the samples, they were oven dried (40°C), and size fractioned to support other metallurgical test work. The remaining grain size fractioned samples were subsequently recomposited to support their use in the geochemical test program at that time. Pre-CND supernatant samples were also collected at this time from the six samples of LP Zone whole tailings.
- Five whole tailings samples that were subjected to CND testing. These five samples were re-generated from five of the original nine ore composite samples and included three samples of LP Zone tailings and one sample each of Limb Zone and Hinge Zone tailings. Data for some samples were considered as paired samples because they were generated from the same original ore composite. Whole tailings supernatant (post-CND) samples were also collected from these five samples.

Paste Backfill

Post-CND whole tailings representative of the LP Zone was used to prepare samples of paste backfill according to Project engineering specifications for underground backfill. The whole tailings sample used

to prepare the backfill was previously characterized and selected by Great Bear Resources to be representative of the life of mine tailings feed to the paste plant.

Paste backfill was prepared at the Global ARD laboratory in Burnaby, British Columbia in 2024 using simulated whole tailings mixed with 3% (by dry weight) Terraflow binder supplied by Minefill Australia. Water was added to achieve a solids content of 72.5% w/w, and the mixture was homogenized into a paste using a high-shear mixer. Backfill was cured for 28 days at 35°C, with relative humidity above 95% maintained throughout the curing period.

The prepared backfill sample and samples of the whole tailings and binder (which were used in the preparation of backfill) were analyzed separately as part of the static test program.

6.2.3 ANALYTICAL TEST METHODS AND SCREENING APPROACH

Static testing was conducted at the Global ARD laboratory in Burnaby, British Columbia. A summary of the static tests completed on tailings is provided in Table 6.2-2. An overview of the static test methods used for the ML / ARD assessment is discussed below. Further details on these methods and sample preparation information are presented in Section 4.3 and Appendix A.

ABA testing was conducted on all samples to evaluate the balance of potentially acid generating and acid neutralizing minerals in the samples.

- ABA testing included determination of paste pH, total S by Leco furnace, sulphate S by HCl leach followed by Leco furnace or turbidimeter, sulphide S by difference (total S – sulphate S), Modified NP [11], TC by Leco furnace and TIC. CarbNP was calculated from TIC. Supplemental test work was completed on the whole tailings samples produced in 2022 and 2023 to confirm sulfur speciation, including sulphate S by Na_2CO_3 leach and sulphide S by HNO_3 leach.
- TIC was analyzed by several methods including HCl leach and Leco furnace for six of the desulphurized tailings samples, eight of the concentrate tailings samples, and the prepared paste backfill sample. TIC was analyzed by $HClO_4$ leach and coulometer for the whole tailings samples, seven samples of desulphurized tailings and nine samples of concentrate tailings. There appeared to be an interference with the Leco furnace analysis for TIC for the concentrate tailings. This was suspected to be related to the presence of metallurgical reagents in the samples. Therefore, all samples from 2024 were also analyzed by $HClO_4$ leach and coulometer determination to measure their TIC content.
  - TIC content by $HClO_4$ leach and coulometer was consistent with HCl leach for the desulphurized tailings samples that were analyzed by both methods. CarbNP was calculated from TIC by HCl leach and Leco where available (F9-RO, F7-RO, F8-RO, F4-RO, F5-RO and F6-R-RO). CarbNP was calculated from TIC by $HClO_4$ leach and coulometry for the remaining tailings samples (F1-Ro Tailings, F1-Ro Concentrate, C01-F9, C02-F7, C03-F8, C04-F4, C05-F5R, C06-F6R, CO2-F1 and CO2- F2).
  - The sample of Terraflow binder (used in the backfill) could not be analyzed for TIC using the Leco furnace. Due to the nature of the sample (slag-based cement binder), it appeared incompatible with HCl leach and high temperatures and melted when analysis was attempted. This sample was therefore analyzed by $HClO_4$ leach and coulometer.

NAG testing was conducted on seven desulphurized tailings samples, one sample of concentrate tailings, and nine whole tailings samples. Analysis of NAG leachate chemistry is also available for the whole tailings samples.

- NAG pH results were screened against NAG pH criteria for PAG and NPAG materials (AMIRA 2002) and assessed in conjunction with NPR values from ABA testing.

[11] MEND 1991 method, based on the 1989 Lawrence Modified NP method.

- NAG leachates were analyzed for pH, conductivity, acidity, sulphate, chloride, fluoride, total dissolved P, and dissolved metals (Hg, Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Tl, U, V, W and Zn).
- NAG leachate chemistry was compared to screening values to identify parameters of potential interest under acidic leaching conditions. The screening analysis included comparison of the NAG leachate chemistry to PWQO values for the protection of aquatic life, including both in-place PWQO values and interim PWQO values. The NAG leachate test and screening approach is not a direct representation of site water quality and comparisons to screening values hold no regulatory significance.

Solid phase elemental content analysis was conducted on all samples by aqua regia digestion and ICP-MS scan for environmental screening purposes. Results were compared to 10 times the crustal abundance values presented in Price (1997) for screening purposes. Sample concentrations greater than the screening value were considered enriched in those elements. This approach is used to screen the samples for elemental enrichment based on standard screening values and does not provide a direct assessment of metal leaching potential or resulting drainage water quality. Elements that were enriched in the solid phase were given additional consideration in subsequent metal leaching assessments (SFE, NAG, and kinetic testing).

Post-CND supernatant (decant water) samples were analyzed to assess the quality of process water that could be discharged with tailings during mine operations. Supernatant was also analyzed prior to CND to evaluate the influence of bench scale reagent addition on the water quality of the post-CND supernatant samples.

- The tailings supernatant was analyzed for pH, conductivity, acidity, alkalinity, sulphate, chloride, fluoride, nitrate, nitrite, ammonia, total cyanide, weak acid dissociable cyanide, free cyanide, cyanate, thiocyanate, total dissolved P by colourimetry, Hg by CVAA and dissolved metals by ICP-MS (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mo, Na, Ni, Pb, Sb, Se, Sr, Tl, U, V, W and Zn).
- Results were compared to screening values to identify parameters of potential interest. The screening analysis included comparison of the SFE leachate chemistry to both in-place PWQO values and interim PWQO values.
- It is noted that the bench-scale CND process is not directly representative of the field-scale process. The use of the data as an indicator of potential future process water quality is considered preliminary and for screening purposes only.

SFE testing was conducted on selected samples including seven samples of post-CND desulphurized tailings, four samples of post-CND concentrate tailings and nine samples of pre-CND whole tailings. The SFE test is a screening test to assess the potential release of soluble metals during the initial (e.g., short-term) stages of weathering.

- Leachates from the desulphurized tailings, one sample of concentrate tailings and all pre-CND whole tailings were analyzed for pH, conductivity, acidity, alkalinity, sulphate, nitrate, nitrite, ammonia, total cyanide, weak acid dissociable cyanide, free cyanide, cyanate, thiocyanate, total dissolved P by colourimetry, Hg by CVAA and dissolved metals by ICP-MS (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mo, Na, Ni, Pb, Sb, Se, Sn, Sr, Tl, U, V, W and Zn).
  - To preserve mass for kinetic testing, three of the concentrate tailings samples were analyzed for a reduced set of parameters including pH, conductivity, acidity, alkalinity, sulphate, nitrate, nitrite, ammonia, Hg by CVAA and dissolved metals by ICP-MS (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mo, Na, Ni, Pb, Sb, Se, Sn, Sr, Tl, U, V, W and Zn).
- Modified SFE testing, maintaining a 3:1 mass ratio of deionized water to sample, was conducted on three of the concentrate tailings samples (C02-F7, C04-F4 and C02-F1) due to limitations in sample mass available. Leachates from these samples were analyzed for pH, conductivity, acidity, alkalinity, sulphate, chloride, fluoride, nitrate, nitrite, Hg by CVAA and dissolved metals by ICP-MS (Ag, Al, As, B, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mo, Na, Ni, Pb, Sb, Se, Sn, Sr, Tl, U, V, W and Zn). Total dissolved P, ammonia and cyanide species were not analyzed due to low sample volume.

- Leachate chemistry was compared to screening values to identify parameters of potential interest for metal leaching. The screening analysis included comparison of the SFE leachate chemistry to in-place PWQO values and interim PWQO values. The SFE test and screening approach is not a direct representation of mine water quality and comparisons to screening values hold no regulatory significance.

Mineralogical testing using R-XRD was conducted on six desulphurized tailings samples, five samples of whole tailings, one sample each of the whole tailings and Terraflow binder used in the preparation of paste backfill, and one sample of prepared paste backfill. R-XRD analysis was also conducted on one composite sample of concentrate tailings that was utilized for kinetic testing.

6.2.4 QUALITY ASSURANCE AND QUALITY CONTROL

Upon receipt, laboratory data quality was reviewed according to the methods presented in Section 4.6. Where provided, this included review of laboratory QA / QC protocols such as replicates, duplicates, and certified reference materials.

Relative percent differences were found to be within acceptable limits (<10%) and were usually within 5% with rare exceptions that tended to occur for parameters that were near the analytical detection limit.

Comparison of NPR values and NAG pH generally showed good alignment for all samples, where available.

Charge balances, method blanks and method spikes for aqueous analyses returned QA / QC data that was within expected benchmarks with rare exceptions that were also associated with low concentrations near the analytical detection limit.

Differences were noted for the Terraflow binder sample between carbon results in ABA testing and calculated carbon based on R-XRD results. Specifically, the R-XRD results showed notably higher calcite than expected based on CarbNP data from ABA testing. Mass balance calculations for the whole tailings, binder and the prepared paste also suggested that CarbNP was underestimated by ABA and that the CarbNP of the Terraflow binder was on the order of 400 kg $CaCO_3$/t. This aligned with the calculated CarbNP based on the calcite content of the sample. Aqua regia calcium by ICP-MS aligned with R-XRD calcite. The CarbNP results from ABA testing were therefore attributed to analytical challenges due to sample composition. Carbon content based on the R-XRD results was therefore used in place of ABA results for this specific sample.

6.2.5 ACID GENERATION POTENTIAL

Key static testing results are summarized below and shown in Figure 6.2-2 through Figure 6.2-5. Additional results and data are provided in Appendix G.

Desulphurized Tailings

Samples of desulphurized tailings were NPAG and had low concentrations of total S, ranging from 0.07 to 0.23% (median 0.18%; Table G-1). Sulphate S concentrations were low relative to the total S concentrations, ranging from 0.02 to 0.12% in the desulphurized tailings samples.

The relationship between total S and sulphide S is presented in Figure 6.2-2. In general, S was predominately present as sulphide in the desulphurized tailings, however the proportion of sulphide S relative to sulphate S was somewhat variable in individual samples due to the low S content (and sulphate S contents near the detection limit).

- The R-XRD results (discussed further below) support the results of S speciation testing, whereby sulphides represent the predominant form of S in the samples, with no identified sulphate phases. The S contents of the samples were too low to reliably confirm sulphide phases by R-XRD and a detailed mineralogy program has been initiated to provide additional information regarding sulphide mineralogy in the desulphurized tailings.

The Modified NP content of desulphurized tailings samples ranged from 11 to 45 kg $CaCO_3$/t (median of 27 kg $CaCO_3$/t). The relationship between NP and CarbNP is presented in Figure 6.2-3.

- CarbNP was slightly lower than Modified NP, suggesting that while carbonate minerals comprise most of the neutralization capacity in the desulphurized tailings samples, some NP may also be contributed by aluminosilicate phases. This was confirmed by R-XRD testing which identified calcite as the dominant carbonate mineral in all six samples, and high levels of plagioclase feldspar. Low levels (<0.5%) of other carbonate minerals (e.g., siderite and ankerite-dolomite) were also identified as possibly present by R-XRD analysis, although the presence of these phases could not be completely resolved in the spectra.

Acid generation potential was evaluated based on the sample's NPR (Table G-1), including NPR (NP/AP) and CarbNPR (CarbNP/MPA). As some samples contained lower levels of CarbNP, CarbNPR is considered a more appropriate approach to classify the acid generation potential of the samples. Results based on CarbNPR are discussed below and additional information on NPR values is provided for completeness.

- All of the desulphurized tailings samples were classified as NPAG. NPR values were consistent with CarbNPR values (Table G-1), and classification of the samples was consistent for both approaches (Figure 6.2-4 and Figure 6.2-5).

Acid generation potential was also evaluated based on results of single addition NAG pH testing that was completed on all seven desulphurized tailings samples. All seven desulphurized tailings samples were classified as NPAG by the NAG test, consistent with the classification of the samples by ABA testing (Table G-2).

Concentrate Tailings

Results of the ABA analyses are presented in Table G-1 (Appendix G), and key results are summarized below. The tested samples of concentrate tailings were PAG.

The concentrate tailings samples had elevated concentrations of total S as expected due to the flotation process, ranging from 21 to 42% (median 32%). Sulphate S concentrations were low relative to the total S contents of the samples, at 0.03 to 2.1%. The relationship between total S and sulphide S is presented in Figure 6.2-2 and indicated that S was predominantly present as sulphide S in the concentrate tailings.

- Due to limitations in sample mass available, mineralogical analysis by R-XRD was completed on a composite sample of concentrate tailings (generated from the individual samples) that was also used for the kinetic test program (Section 6.3; COMP-S). Results indicated that pyrite represented the dominant sulphide mineral in the concentrate tailings (70 wt.%), with small amounts of pyrrhotite (1.6 wt.%) and chalcopyrite (0.6 wt.%) also present. Gypsum was the only sulphate mineral identified and was present at a trace level (0.6 wt.%). These results are consistent with ABA testing. Detailed mineralogical testing is underway for concentrate tailings.

The Modified NP content of the concentrate tailings samples ranged from 3.9 to 119 kg $CaCO_3$/t (median of 51 kg $CaCO_3$/t). CarbNP was generally similar to or slightly lower than Modified NP for most samples of concentrate tailings (Figure 6.2-3). This suggests that carbonate minerals comprise most of the neutralization capacity in the samples. For samples with NP <10 kg $CaCO_3$/t, Modified NP was slightly higher than CarbNP indicating that non-carbonate minerals may contribute some of the NP in these samples. Alternatively, one sample with Modified NP of 10 kg $CaCO_3$/t had CarbNP that was slightly higher than NP, indicating the sample may contain a small amount of non-net-neutralizing carbonate minerals.

Mineralogical analysis conducted on the composite sample of concentrate tailings identified a small amount of calcite (2.2 wt.%) which generally aligned with the amount of CarbNP detected in this sample (31 kg $CaCO_3$/t). Non-net neutralizing carbonate minerals such as ankerite-dolomite and / or siderite were not identified. These results were expected based on the relationship between CarbNP and Modified NP in ABA results, which indicated that most of the NP was derived from carbonate minerals.

Acid generation potential was evaluated based on the samples' CarbNPR. Results are discussed below and presented in Figure 6.2-4 as well as Table G-1 (Appendix G). NPR values are shown in Table G-1 and additional information on NPR values is provided below for completeness.

- All of the concentrate tailings samples were classified as PAG (Figure 6.2-4). CarbNPR values for these samples were less than 1.
- NPR values were consistent with CarbNPR values (Table G-1), and classification of the samples was consistent for both approaches (Figure 6.2-5).

Acid generation potential was also evaluated by NAG pH testing (single addition) on one concentrate tailings sample. The concentrate tailings sample was classified as PAG by the NAG test (Table G-2). This is consistent with the classification of the sample by ABA testing.

For completeness, the ABA results for the desulphurized tailings and concentrate tailings samples presented above were compared to the ABA results for the ore composites used to generate the tailings. Selected data are shown in Table 6.2-3.

- Higher Modified NP values were noted for the concentrate tailings relative to the desulphurized tailings and ore composites (Table 6.2-3). The CarbNP and Modified NP content of the desulphurized tailings samples was generally consistent with the CarbNP and Modified NP content of the ore composites, as shown in Table 6.2-3. However, most samples of concentrate tailings had CarbNP and Modified NP contents that were several times greater than the NP content of their respective ore composite samples. NP of the concentrate tailings samples were analyzed in duplicate (where sample quantity allowed) and the results were reproducible.
- Higher Modified NP and CarbNP values for the concentrate tailings relative to the desulphurized tailings and ore composites may be related to the flotation process. Metallurgical studies are continuing and will provide additional samples of concentrate tailings for further analysis including kinetic testing. For current Project purposes the concentrate tailings is assumed to have a low NP content (e.g., similar to the desulphurized tailings).

Whole Tailings

Whole tailings samples were produced from nine ore composites, including nine samples of pre-CND whole tailings and five samples of post-CND whole tailings. Data for five samples of the pre- and post-CND whole tailings were considered as paired samples because they were generated from the same original ore composite.

Results of the ABA analyses are presented in Table G-1 (Appendix G) and key results are summarized below. ABA test results were generally consistent among the paired samples (C01 / CND-1, C02 / CND-2, C03 / CND-3, C08 / CND-4 and C09 / CND-5). An average of the ABA test results was used to represent the paired samples from the 2022 and 2023 programs discussed below.

Whole tailings [12] samples comprising material representative of the bulk of Project ore feed (e.g., the LP Zone) were PAG. Samples representing the Hinge Zone ore feed were NPAG, and samples from the Limb Zone had an uncertain acid generation potential (e.g., NPR 1 to 2). The whole tailings samples overall had variable S contents, ranging from 0.4% to 4% in all whole tailings samples tested, and from 0.7% to 2.6% (median 1.2%) in samples representative of the LP Zone.

Sulphate S concentrations were low overall and relative to sulphide S, ranging from 0.01 to 0.03% in the whole tailings samples (Figure 6.2-2). The presence of S as predominantly sulphide was supported by additional S speciation testing completed on the samples. Results of S speciation testing are included in Table G-1 of Appendix G.

[12] ABA results of whole tailings samples prepared in 2022 and 2023 were generally consistent among the paired samples. An average of the ABA test result was used to represent the overall result for the paired samples C01 / CND-1, C02 / CND-2 and C03 / CND-3.

Mineralogical testing by R-XRD conducted on the five samples of post-CND tailings produced in 2023 further confirmed this, with no sulphate minerals identified in any of the samples. Sulphide was primarily present as pyrite in the LP Zone samples, and as pyrite and pyrrhotite in the Limb and Hinge Zone samples.

The samples had variable Modified NP contents, ranging from approximately 15 to 150 kg $CaCO_3$/t (Table G-1). The Modified NP content of the LP Zone samples (n=6) ranged from approximately 15 to 50 kg $CaCO_3$/t (median 30 kg $CaCO_3$/t). The highest Modified NP value was observed for the Limb Zone sample, at approximately 150 kg $CaCO_3$/t. The Modified NP content of the Hinge Zone samples (n=2) was approximately 100 kg $CaCO_3$/t.

The relationship between Modified NP and CarbNP is presented in Figure 6.2-3 and indicated the following:

- The LP Zone samples (n=6) generally had a low CarbNP content, ranging from 7.5 to 33 kg $CaCO_3$/t (median 21 kg $CaCO_3$/t), consistent with R-XRD results which identified low quantities of carbonate minerals. CarbNP in these samples was lower than the Modified NP for most of the samples (Figure 6.2-3). This suggests that though carbonate minerals comprise most of the neutralization capacity in the samples, some samples contained a notable proportion of non-carbonate neutralization capacity (potentially from the high proportion of plagioclase feldspar identified in these samples).
- The Hinge Zone samples (n=2) had a higher NP content (e.g., on the order of 100 kg $CaCO_3$/t), and the CarbNP for these samples was similar to or slightly lower than the Modified NP (Figure 6.2-3). This suggests that most of the neutralization capacity in these samples was present as carbonate minerals.
- The Limb Zone sample had the highest NP content among the sample set (150 kg $CaCO_3$/t). The CarbNP value for this sample was similar to, but slightly greater than the NP, suggesting that some of the neutralization potential in the sample may be present as non-net neutralizing carbonate minerals (e.g., Fe carbonates, potentially including siderite or ankerite; Figure 6.2-3). This was consistent with mineralogical results for this sample, which identified ankerite-dolomite and potential trace amounts of siderite in the sample.

Acid generation potential was evaluated based on the sample's CarbNPR. Results based on CarbNPR are discussed below and presented in Figure 6.2-4 as well as Table G-1 (Appendix G). NPR values are shown in Table G-1 and additional information on NPR values is provided below for completeness.

- The LP Zone and Limb Zone samples were classified as PAG.
- This was generally consistent with the classification by NPR, with the exception of one isolated sample from the LP Zone (C05) which had higher non-carbonate neutralization capacity and was classified as NPAG (Figure 6.2-5).
- All samples from the Hinge Zone were classified as NPAG by both approaches.

Acid generation potential was also evaluated by NAG pH testing (single addition). Testing was completed on 14 samples of whole tailings. Results for the single-addition NAG test are shown in Table G-2.

Results were reasonably consistent among the paired samples and the average NAG pH value was generally used for paired samples. However, results for sample pair C03 / CND3 were inconsistent, whereby sample C03 was classified as PAG by the NAG pH test (NAG pH of 2.9) and sample CND3 was classified as NPAG by the NAG pH test (NAG pH 10.3). This difference was attributed to the small sample size (2.5 g) used for this analysis, and potential subsample variability at this scale of sample; results for other analytical tests for this pair of samples generally showed reasonable agreement. Therefore, NAG pH test results for samples C03 and CND3 were considered individually.

The results of NAG testing for the LP Zone samples were as follows:

- Three of the LP Zone samples (C02 / CND-2, C03 and C04) had a NAG pH <4.5 and were classified as PAG. This was consistent with the classification of these samples based on ABA testing (CarbNPR ≤2).

- Four of the LP Zone samples (C01 / CND-1, CND-3, C05, C06) had a NAG pH >4.5 and were classified as NPAG by the NAG test. However, these samples were classified as PAG based on ABA testing (CarbNPR ≤2).
  - C06 had a S content >1% and inconsistent results between the NAG test and ABA testing were attributed to incomplete oxidation of S during the single addition NAG test.
  - NAG pH and ABA test results for C05 were inconsistent: C05 was classified as NPAG based on its NAG pH value, PAG based on its CarbNPR value, and NPAG based on its NPR value, due to its higher Modified NP content. Together these results suggest that some of the non-carbonate neutralization capacity in this sample may be reactive and may support its classification as NPAG. The observed results appear to be isolated to this single sample.
  - The other two samples with inconsistent results by the two methods (C01 / CND-1, CND-3) contained lower levels of S (approximately 0.7% to 0.8%), inferred to be present as sulphide S based on ABA testing. Inconsistent results for these samples were attributed to subsample variability or the presence of slow-reacting sulphide phases (e.g., produce little acidity). As previously noted, pyrrhotite is present in sample C01 / CND1. Pyrrhotite may undergo incomplete oxidation during the NAG test, giving rise to the observed result for these samples.

The two Hinge Zone samples had NAG pH >4.5 and were classified as NPAG. These samples were also classified as NPAG by ABA testing. Hinge Zone tailings are planned to comprise a small proportion of the overall Project tailings volume.

The Limb Zone sample had a NAG pH >4.5 and was classified as NPAG by the NAG test. However, the sample was classified as PAG by ABA testing. The apparent low reactivity during the single addition NAG test was attributed to elevated levels of S (e.g., >1%) and the presence of elevated levels of pyrrhotite, both of which can be associated with the incomplete oxidation of sulphides during the test.

Paste Backfill

Results of the ABA analyses completed on the prepared paste backfill samples and the whole tailings and Terraflow binder used in preparation of the paste backfill, are presented in Table G-1 (Appendix G) and key results are summarized below.

- The whole tailings and prepared paste backfill samples had similar total S contents of approximately 1.1%, consistent with the S content observed for LP Zone whole tailings overall. S speciation testing indicated that S was predominantly present as sulphides in these samples, with low sulphate S contents, ranging from <0.01 to 0.03% (Figure 6.2-2).
- The total S content of the Terraflow binder sample was slightly higher (1.4%). Sulphate S was found to comprise all of the S present in the sample of Terraflow binder.
- The above results for S speciation testing are consistent with R-XRD results which identified sulphide minerals (e.g., pyrite and pyrrhotite) in the whole tailings and prepared paste backfill samples. No sulphate mineral phases were detected for those samples. Mineralogy results for the Terraflow binder identified sulphate mineral phases including gypsum and ettringite. Sulphide minerals were not detected in the sample of Terraflow binder analyzed by R-XRD.

The Modified NP content of the whole tailings used in backfill preparation was 37 kg $CaCO_3$/t, with most of the neutralization capacity contributed by carbonates (CarbNP 25 kg $CaCO_3$/t). The characteristics of the sample were consistent with R-XRD data and similar to other samples of LP Zone whole tailings (approximately 3 wt.% calcite).

ABA results for the Terraflow binder indicated that the sample had a CarbNP of 69 kg $CaCO_3$/t and a Modified NP of 991 kg $CaCO_3$/t (Figure 6.2-3). However, mineralogical analysis (R-XRD) indicated that the sample had a high proportion of calcite (37 wt.%), suggesting that the CarbNP for the sample was on the order of 375 kg $CaCO_3$/t. Mass balance calculations for the whole tailings, binder and the prepared paste also suggested that CarbNP was underestimated by ABA and that the CarbNP of the Terraflow binder was on the order of 400 kg $CaCO_3$/t. This aligned with the calculated CarbNP based on the calcite content of the sample. The calculated CarbNP (414 kg $CaCO_3$/t) was therefore used to represent the

CarbNP of the Terraflow binder. Other Leco-based analyses for the Terraflow binder demonstrated analytical challenges as summarized in Section 6.2.3. Comparison of CarbNP vs Modified NP of the Terraflow indicated that the binder has considerable carbonate neutralization capacity and a notable amount of non-carbonate neutralization capacity. Non-carbonate neutralization capacity was attributed to aluminosilicates based on mineralogy.

The prepared paste backfill sample had slightly more Modified NP than the whole tailings, with a Modified NP of 60 kg $CaCO_3$/t and a CarbNP of 37 $CaCO_3$/t, indicating that the sample contained both carbonate neutralization capacity and non-carbonate neutralization capacity. As discussed above, the prepared backfill sample is expected to contain small quantities of a highly reactive source of neutralization capacity. The slight increase of Modified NP content following preparation of the paste compared to the whole tailings material aligns with the characteristics of the Terraflow binder used in the paste.

The acid generation potential of the prepared backfill was evaluated based on the sample's neutralization potential ratio. Results based on CarbNPR are discussed below and presented in Table G-1 and Figure 6.2-4 (Appendix G). NPR values are shown in Table G-1 and Figure 6.2-5 and additional information on NPR values is provided below for completeness.

- The sample of prepared paste backfill had a CarbNPR of 1 and NPR of 1.8 and was classified as PAG. This is consistent with the ABA classification of the whole tailings used in preparation of the backfill.
- Kinetic testing is underway to confirm the acid generation potential of prepared backfill.

6.2.6 ELEMENTAL CONTENT

Elemental content analysis is used to quantify the concentration of elements in solid phases (e.g., minerals), but does not provide a direct assessment of metal leaching potential or drainage water quality. The solid phase elemental content of the samples was compared to 10 times the average crustal abundance value for a given element (Price 1997) for screening purposes. Samples with elemental concentrations greater than these screening values were considered enriched in those elements.

The information presented below focuses on selected elements and includes those that are of key relevance to ML / ARD. All results are provided in Table G-3 (Appendix G).

Results were reviewed and elemental enrichment was based on concentrations above the analytical detection limit where those detection limits were lower than or equal to 10 times the crustal abundance values.

Desulphurized Tailings

Key results for the desulphurized tailings samples (n=7) are summarized below:

- Mercury was below the screening value (0.85 mg/kg) in all desulphurized tailings samples.
- Arsenic concentrations were slightly greater than the screening value (18 mg/kg) in three of the desulphurized tailings samples, on the order of 25 to 40 mg/kg.
- Tungsten concentrations were slightly greater than the screening value (13 mg/kg) in two of the desulphurized tailings samples.

Concentrate Tailings

Key results for the concentrate tailings samples (n=9) are summarized below. Due to the purposeful high sulphide content of these samples (due to flotation), numerous elements were above screening values:

- Concentrations of Ag, As, Cd, Cu and Se were greater than their respective screening values in all concentrate tailings samples.
- Some concentrate tailings samples had concentrations greater than their respective screening values for Pb (n=8), Mo (n=7), Zn (n=6), Sb (n=4) and W (n=2).
- Mercury was below the screening value (0.85 mg/kg) in all concentrate tailings samples.

Review of molar ratios in elemental content data suggested that Fe sulphides were the primary sulphide minerals present in the samples. This was supported by mineralogical data from R-XRD analysis completed on a composite sample of the concentrate tailings, which identified pyrite as the predominant sulphide mineral present (70 wt.%). Detailed mineralogical analysis is underway to confirm sulphide mineral phases in the concentrate tailings.

Whole Tailings

Key results for the whole tailings samples (n=9) are summarized below.

- Paired samples generally had consistent results, and the average of the paired samples was therefore used to represent the overall result. The majority of elements were below screening values in all samples with the following exceptions:
  - Selenium concentrations were greater than the screening value (0.5 mg/kg) in all of the samples (n=9). In most of the samples, Se concentrations were marginally greater than the screening value; however, several samples had Se contents on the order of 1 to 4 mg/kg. This included several samples from the LP Zone and the single Limb Zone sample. A relationship between the S and Se content of the samples was observed, whereby samples with a higher S content had a higher Se content.
  - Arsenic concentrations were greater than the screening value (18 mg/kg) in most samples (n=8). Arsenic concentrations ranged from approximately 20 to 300 mg/kg for the LP Zone and Hinge Zone samples. The single Limb Zone sample had an As content of approximately 0.15% (1,500 mg/kg). Some samples with a higher S content had a higher As content, however this trend was not consistent among the dataset. The As content of the samples was generally notably lower than the S content of the samples on a molar basis, suggesting that arsenopyrite is not likely to be an important sulphide phase in the samples. No As minerals were identified in R-XRD for these samples.
  - Tungsten was above the screening value (13 mg/kg) in three samples.
  - Two LP Zone samples had Cd (n=1) and Mo (n=1) concentrations above the respective screening values for these elements.
- All whole tailings samples had Hg concentrations that were below screening values.

Paste Backfill

Elemental content analysis of the paste backfill sample showed:

- Arsenic concentrations were greater than the screening value (18 mg/kg) in the prepared backfill sample, with concentrations of 195 mg/kg (the same as the As concentration in the whole tailings sample that was used in preparation of the backfill).
- Selenium and W concentrations were greater than the screening values (0.5 mg/kg and 13 mg/kg) in the prepared backfill and were similar to the concentrations in the whole tailings used to prepare the backfill.
- Mercury was below screening values (0.85 mg/kg).

6.2.7 SCREENING ASSESSMENT OF PROCESS WATER

Supernatant data was inspected to assess process water quality that could be discharged with the tailings during mine operations. It is recognized that the bench-scale CND process is not consistent with field scale operations and this assessment is considered preliminary.

Test results are shown in Table G-4 (Appendix G).

Desulphurized Tailings

Supernatant from six of the desulphurized tailings samples (post-CND) was analyzed. A summary of parameters with concentrations greater than in-place and interim PWQO screening values is provided in Table 6.2-4. The following additional observations are provided with respect to qualitative screening values:

- The pH of the desulphurized tailings supernatant samples ranged from 6.4 to 7.4, with one sample below the PWQO screening value for pH (6.5).
- The sulphate concentration of the supernatant samples ranged from 973 to 1,374 mg/L (median 1,209 mg/L) in desulphurized tailings. The sulphate concentration of the pre-CND supernatant was notably lower (e.g., 70 to 100 mg/L, Table G-4) and the increase in sulphate was attributed to reagents used in the CND process.
- Mercury in all post-CND supernatant samples was below the PWQO screening value (0.0002 mg/L) and the analytical detection limit (0.000005 mg/L).
- Metal concentrations in desulphurized tailings supernatant were low for the majority of elements, and notably lower than the concentrations in pre-CND supernatant for equivalent samples (Table G-4). A summary of elements that had concentrations in supernatant greater than qualitative screening values is presented in Table 6.2-4.
- Arsenic concentrations in the supernatant varied and appeared to be influenced by As mineralogy, as samples with a higher solid phase As:S molar ratio had higher As concentrations in their supernatants (Figure 6.2-6). Similar trends have been observed for mine rock. Arsenic concentrations generally ranged from 0.0003 mg/L to 0.042 mg/L (median 0.003 mg/L). Most samples fell within that range however one sample (F8-RO) had higher supernatant As and was inferred to contain cobaltite-gersdorffite based on its As:S molar ratio and apparent As leaching behaviour. A detailed mineralogy program is currently underway for the tailings to confirm the influence of mineralogy on metal release.

Concentrate Tailings

Supernatant from six of the concentrate tailings samples, post-CND, was analyzed.

A summary of parameters with concentrations greater than screening values is provided in Table 6.2-5. The following additional observations are provided with respect to qualitative screening values:

- The pH of the concentrate tailings supernatants ranged from 7.2 to 7.7.
- The sulphate concentration of the supernatant of concentrate tailings samples ranged from 844 to 1,182 mg/L (median 1,087 mg/L). As previously mentioned, the sulphate concentration of the pre-CND supernatant was notably lower (e.g., 70 to 100 mg/L, Table G-4) and the increase in sulphate was attributed to reagents used in the bench scale CND process.
- Mercury in all concentrate tailings supernatants was below the PWQO screening value (0.0002 mg/L) and the analytical detection limit (0.000005 mg/L).
- Metal concentrations were lower than observed in pre-CND supernatant for equivalent samples. Some elements greater than qualitative screening values were observed in the supernatant samples as presented in Table 6.2-5. Concentrations of P above screening values were attributed to reagent use during flotation.
- Arsenic concentrations in the tailings supernatants varied and appeared to be influenced by As mineralogy of the tailings, as samples with a higher solid phase As:S molar ratio had higher As concentrations in their supernatants (Figure 6.2-6). Supernatant As concentrations in concentrate tailings samples ranged from 0.0005 mg/L to 0.036 mg/L with most samples falling within that range. One concentrate tailings sample (C03-F8) had an elevated As concentration (0.36 mg/L; Table G-4), which was also observed in the supernatant of this sample's desulphurized tailings counterpart (F8-RO) discussed above and was inferred to contain cobaltite-gersdorffite. A detailed mineralogy program is underway to provide additional information.

Whole Tailings

Post-CND supernatant from the whole tailings samples was also analyzed (n=11).

The test results are shown in Table G-4 (Appendix G) and summarized in Table 6.2-6. Results were compared to screening values, where applicable, for assessment purposes. Key results for the post-CND supernatant are summarized below:

- The pH of the post-CND supernatant samples ranged from approximately 6.9 to 7.8. Sulphate concentrations were on the order of 1800 mg/L in most samples; however, the Limb Zone supernatant had sulphate concentrations on the order of 3700 mg/L, consistent with the higher sulphide content of the Limb Zone tailings relative to the other samples. One sample of supernatant from LP Zone post-CND tailings also had a high sulphate value (4200 mg/L). This sample was generated during a separate metallurgical program that reported challenges with the CND process and excess reagents being used.
- Copper concentrations were greater than screening values in most of the post-CND supernatant samples. This is due to the nature of the CND process which used $CuSO_4$ as a reagent.
- As concentrations in supernatant were above the interim PWQO screening value in four out of six samples. The highest supernatant concentrations (approximately 0.01 mg/L) were observed for samples with higher As:S ratios, indicating that supernatant concentrations may be influenced by the As mineralogy of the ore feed. The As:S ratios in whole tailings were consistent with those in the ore composites used in preparation of the samples.
- Other metals that were above screening values in post-CND supernatant for whole tailings included As, Cd, Cr, Co, Fe, Sb, Mo and U.

6.2.8 SHAKE FLASK EXTRACTION

SFE testing was conducted on selected samples of tailings as presented in Section 6.2.3. The concentrations in SFE leachates were compared to in-place and interim PWQO screening values to identify parameters of potential interest for metal leaching. Test results are summarized in Table 6.2-7. Complete test results are presented in Table G-5 (Appendix G).

Desulphurized Tailings

SFE testing was conducted on all seven desulphurized tailings samples. Key observations regarding SFE leachates with respect to qualitative screening values are summarized below:

- The pH of the desulphurized tailings SFE leachates was weakly acidic, with pH on the order of 6.3 to 6.6 for all tested samples.
- Sulphate concentrations in the leachates of the desulphurized tailings samples ranged from 61 to 214 mg/L. Samples with higher sulphide content generally had higher sulphate concentration in the SFE leachates.
- Metal concentrations in the SFE leachates were typically below the qualitative screening values for most metals (Table 6.2-7).
  - Arsenic concentrations were below the in-place PWQO (0.1 mg/L) for all desulphurized tailings samples tested. Arsenic concentrations were slightly greater than the interim PWQO screening value (0.005 mg/L) in SFE leachate of two desulphurized tailings samples. A relationship was noted between As concentrations in SFE leachates and the solid phase As:S content of desulphurized tailings samples, whereby higher As in leachate was associated with higher As:S ratios in the solid phase (Figure 6.2-7). The two samples with As concentrations greater than the interim PWQO screening value had a higher As:S molar ratio compared to the other desulphurized tailings samples. This suggests that As host mineralogy is influencing As release from these samples. Detailed mineralogical testing of the tailings is underway to confirm As host mineralogy.

- Mercury was below the analytical detection limit (0.000005 mg/L) for all desulphurized tailings samples.

Concentrate Tailings

SFE testing was conducted on four concentrate tailings samples. The other five concentrate tailings samples were not analyzed for SFE testing due to limited sample mass. The SFE leachates were compared to in-place and interim PWQO screening values to identify parameters of potential interest for metal leaching. Test results are summarized in Table 6.2-7. Complete test results are presented in Table G-5 (Appendix G).

Key observations regarding SFE leachates with respect to qualitative screening values are summarized below:

- The pH of the concentrate tailings SFE leachates was circumneutral, with pH ranging from 6.7 to 7.1.
- Sulphate concentrations in the concentrate tailings SFE leachates ranged from 169 to 714 mg/L. A discernable relationship between SFE leachable sulphate and solid phase S content was not observed.
- Metal concentrations in the SFE leachates were typically below the qualitative screening values for most metals (Table 6.2-7).

Whole Tailings

SFE testing was conducted on the pre-CND whole tailings samples (n=9). The SFE leachates were compared to screening values, as applicable, to identify parameters of potential interest for metal leaching. Test results are presented in Table G-5 (Appendix G). Key results are summarized below.

- The pH of the SFE leachates was weakly acidic, with pH on the order of 6.1 to 6.5 for all tested samples.
- Sulphate concentrations were low in the leachates for all samples, ranging from approximately 5 to 50 mg/L. Generally leachate sulphate concentrations increased with increasing solid phase sulphide content.
- Metal concentrations in the SFE leachates were typically below the qualitative screening values for most metals (Table 6.2-7).
    - Aluminium concentrations were greater than the screening value (0.075 mg/L) in most samples (n=8). This is likely an artefact of the testing procedure due to the presence of colloidal Al and is unlikely to be observed under field conditions.
    - Arsenic concentrations were higher than the interim PWQO screening value (0.005 mg/L) in five of the samples, including most of the LP Zone samples (n=4) and one of the Limb samples (n=1). Samples with a higher solid phase As:S molar ratio generally had higher As concentrations in the SFE leachates, as observed for other tailings samples (Figure 6.2-7).

NAG leachate testing was also conducted on all of the whole tailings samples to identify parameters of potential interest under acidic leaching conditions. NAG leachate tests are conducted for screening purposes and are not a direct indicator of drainage quality. Results are presented in Table G-7 (Appendix G).

- Results of NAG leachate testing suggested that Al, Ag, As, Cd, Co, Cr, Cu, Fe, Ni, Pb, Tl, U, V and Zn may be constituents of potential interest under acidic leaching conditions.

6.2.9 BULK MINERALOGY

Mineralogical identification using R-XRD was completed on six desulphurized tailings samples, one sample of concentrate, five samples of whole tailings and backfill (including Terraflow binder). This was done to assess the samples' mineralogical composition including the presence of acid generating and acid neutralizing minerals. Results are provided in Table G-6 (Appendix G), along with chemical formulae

of the minerals discussed below. It is noted that R-XRD can identify minerals at concentrations down to fractions of a weight percent when suitable diffraction conditions exist.

Desulphurized Tailings

Mineralogical testing of the six desulphurized tailings samples identified the following:

- Sulphide minerals could not be clearly resolved in the R-XRD analysis, which reflects the low sulphide content of the samples as determined by other methods. However, the R-XRD analysis identified the possible presence of low levels of pyrite (0.13 wt.%) in one sample and pyrrhotite in two samples (0.36 and 0.53 wt.%). No sulphate minerals were not identified by R-XRD.
- Carbonate minerals included calcite, along with low levels of ankerite-dolomite and siderite likely present.
  - Calcite was the dominant carbonate mineral in all six samples, with concentrations ranging from 0.9% to approximately 4.0 wt.%.
  - Low levels of ankerite-dolomite were likely present in five of the samples, ranging from approximately 0.21 to 0.47 wt.%. Siderite was also indicated in all six samples ranging from 0.12 to 0.40 wt.%.
- The following aluminosilicate phases were identified:
  - Plagioclase (albite) was identified in all samples, with concentrations ranging from approximately 18 to 45 wt.%. Potassium feldspar (microcline) was also identified in all samples with concentrations ranging from approximately 2.5 to 7.0 wt.%.
  - Phyllosilicates were detected in all samples, including illite / muscovite (5.5 to 23 wt.%), biotite (4.7 to 10 wt.%), and clinochlore (1.2 to 2.9 wt.%).
- Quartz was present in all six samples, with concentrations ranging from approximately 32 to 44 wt.%.
- Actinolite was present in four samples, ranging from less than 1 wt.% to 1.2 wt.%.

Concentrate Tailings

Mineralogical analysis was not completed on individual samples of concentrate tailings due to limitations in sample mass. Mineralogical identification using R-XRD was completed on the composite sample prepared for kinetic testing (COMP-S). The sample was prepared from several concentrate tailings samples and is considered generally representative of the concentrate tailings to be produced. Additional concentrate tailings samples will be tested as they are available to confirm mineralogical characteristics of the concentrate. Results are provided in Table G-6 (Appendix G), along with chemical formulae of the minerals discussed below:

- The composite sample had a high proportion of sulphide minerals, as expected. Sulphides were predominantly present as pyrite (70 wt.%) with small amounts of pyrrhotite (1.6 wt.%) and chalcopyrite (0.3 wt.%) also identified in the sample. A small amount (0.6 wt.%) of the sulphate mineral gypsum was also identified in the sample.
- Calcite was the only carbonate mineral identified in the sample with a concentration of 2.2 wt.%. It is noted that the concentrate tailings had a large range in CarbNP / Modified NP content, and the carbonate mineralogy identified in the composite sample is not representative of all individual samples of concentrate tailings.
- The following aluminosilicate phases were identified:
  - Plagioclase (albite, calcian) was identified in the sample with a concentration of 7.7 wt.%.
  - Phyllosilicates were detected in the sample, including illite / muscovite (5.9 wt.%), biotite (1.4 wt.%), and clinochlore (1.0 wt.%).
- Oxide minerals, including quartz (7.7 wt.%) and titanite (1.1 wt.%) were identified in the sample.
- A small amount of actinolite (<1 wt.%) was also identified in the sample.

Whole Tailings

Mineralogical identification using R-XRD was completed on five whole tailings samples to assess their mineralogical composition including the presence of acid generating and acid neutralizing minerals. Results are provided in Table G-6 (Appendix G). Chemical formulae of the minerals discussed below are provided in Table G-6.

Mineralogical differences were observed among the samples from different mineralized zones as presented below, consistent with the varying rock types and mineralization styles that comprise the various zones.

- Pyrite was present in all three LP Zone samples, with concentrations ranging from 0.8 to 4.1 wt.%. One of these samples also contained pyrrhotite (0.6 wt.%). No sulphate minerals were detected. Carbonate minerals were identified in all three LP Zone samples, with concentrations on the order of 1 to 3 wt.%, with trace ankerite-dolomite in two samples. Silicate minerals including plagioclase (identified as albite; 18 to 40 wt.%), muscovite (8 to 22 wt.%), biotite (4 to 9 wt.%), microcline (5 to 8 wt.%), and chamosite (0.5 to 2.5 wt.%) were present in all three samples, as well as quartz (35 to 43 wt.%) and actinolite (0.1 to 1.3 wt.%).
- Pyrrhotite (1.0 wt.%) and pyrite (0.5 wt.%) were identified in the single Hinge Zone sample. No sulphate minerals were detected. Carbonate minerals were identified to include magnesian calcite (8.1 wt.%), calcite (2.8 wt.%), and ankerite-dolomite (0.5 wt.%). Plagioclase (20 wt.%), actinolite (35 wt.%), cummingtonite (2.7 wt.%), biotite (3.1 wt.%), chamosite (3.2 wt.%), ilmenite (1.3 wt.%) and quartz (22%) were also identified in the sample.
- Pyrrhotite (7.4 wt.%) and pyrite (1.6 wt.%) were identified in the single Limb Zone sample. No sulphate minerals were detected. Carbonate minerals were identified to include magnesian calcite (9.3 wt.%), ankerite-dolomite (3.9 wt.%), calcite (3.3 wt.%), and trace siderite (0.4 wt.%). Plagioclase (27 wt.%), actinolite (12 wt.%), cummingtonite (3.6 wt.%), biotite (4.9 wt.%), chamosite (2.2 wt.%), ilmenite (0.8 wt.%), and quartz (23 wt.%) were also identified in the sample.

Paste Backfill

Mineralogical identification using R-XRD was conducted on the post-CND whole tailings and Terraflow binder, and on the prepared paste backfill sample to assess their composition and the presence of acid-generating and acid-neutralizing minerals. The whole tailings sample used to prepare the backfill is mineralogically similar to other whole tailings samples tested. Mineralogy results are provided in Table G-6 (Appendix G). Overall, the mineralogy of the paste backfill closely mirrored the whole tailings composition, as expected.

Key findings from the mineralogical analysis are summarized as follows:

- S was predominately present as sulphide minerals in the whole tailings and prepared paste backfill, and as sulphate minerals in the Terraflow binder, consistent with the findings of ABA testing (see Section 6.2.5).
  - Sulphide minerals identified in the whole tailings and prepared paste backfill include pyrite (1.9 and 1.8 wt.%, respectively) and pyrrhotite (0.3 and 0.4 wt.%, respectively). No sulphide minerals were identified in the sample of Terraflow binder.
  - Sulphate minerals identified in the Terraflow binder include gypsum (10.9 wt.%) and ettringite (1.4 wt.%). No sulphate minerals were identified in the whole tailings or prepared paste backfill.
- Calcite was the only carbonate mineral identified in the samples tested as part of the backfill program. The whole tailings and prepared backfill samples had similar calcite concentrations at 3.2 wt.% and 4.4 wt.%, respectively. The Terraflow binder had a notably higher calcite content at 38 wt.%.
- Feldspars, predominantly albite, comprised approximately 37% of the whole tailings and paste backfill, with microcline present in smaller amounts (<6%). The Terraflow binder did not contain any feldspar minerals.
- Phyllosilicates were identified in the whole tailings and prepared paste backfill samples, including illite - muscovite (approximately 7 wt.%), biotite (approximately 8 wt.%) and clinochlore (1.3 wt.%). The

Terraflow binder did not contain any phyllosilicates, however other silicate minerals were identified in the sample, including merwinite (6.5 wt.%) and hatrurite (37 wt.%)

- Quartz was detected in all three samples, with concentrations ranging from 2.0 wt.% in the Terraflow binder to approximately 34 wt.% in the whole tailings and prepared paste backfill. The Terraflow binder also contained 5.3 wt.% of brownmillerite, a calcium-aluminum-iron oxide mineral.
- Trace amounts (approximately 0.2 wt.%) of actinolite and apatite were also identified in the whole tailings and prepared backfill samples.

6.2.10 KEY FINDINGS

- The desulphurized tailings samples were NPAG and had low concentrations of total S that was predominately identified as sulphide. Modified NP was low to moderate (up to 45 kg $CaCO_3$/t) and was mostly attributed to carbonate minerals (calcite and possible siderite and ankerite-dolomite identified by R-XRD) and non-carbonate minerals (plagioclase feldspar).
- Concentrate tailings samples were PAG based on ABA testing and NAG testing, and had elevated concentrations of total S mainly present as pyrite (70 wt.%). The Modified NP content of the concentrate tailings samples ranged from 3.9 to 119 kg $CaCO_3$/t (median of 51 kg $CaCO_3$/t) and were higher than Modified NP values relative to the desulphurized tailings and ore composites. Additional metallurgical studies are underway and will provide additional samples of concentrate material for confirmation of neutralization capacity.
- Whole tailings samples representative of the Project ore feed (LP Zone) were PAG by ABA testing and NAG testing, with variable S contents predominantly as pyrite. These samples had a low CarbNP content, ranging from 7.5 to 30 kg $CaCO_3$/t (median 21 kg $CaCO_3$/t), consistent with R-XRD results which identified low quantities of carbonate minerals. CarbNP in these samples was typically lower than the Modified NP of the samples (Figure 6.2-3). This suggests that although carbonate minerals comprise most of the neutralization capacity in the samples, some samples contained a notable proportion of non-carbonate neutralization capacity (potentially from the high proportion of plagioclase feldspar identified in these samples).
- The metal leaching and acid generation potential of the paste backfill was similar to the whole tailings from which the paste was prepared. The paste backfill had CarbNP of 37 kg $CaCO_3$/t, a total S content of approximately 1% and an uncertain acid generation potential with a CarbNPR of 1. S was present as sulphide S (pyrite) with minor amounts of possible pyrrhotite (<0.5%). Humidity cell testing is underway to further evaluate the metal leaching and acid generation potential of paste backfill.
- Elemental content of desulphurized tailings, whole tailings and prepared backfill were generally below screening values for the majority of elements. Mercury concentrations were below screening values in all samples, and concentrations of As, Se and W were sometimes above screening values in some samples. Conversely, concentrate tailings had several elements above their screening levels, due to the purposeful high sulphide content of the material. Mercury was below the screening value in all concentrate tailings samples.
- Tailings supernatant samples had sulphate concentrations generally on the order of 1,000 to 2,000 mg/L attributed largely to reagent addition. Supernatant metals concentrations were usually low and below PWQO screening values. Some samples of desulphurized tailings, concentrate tailings and whole tailings showed concentrations of Sb, As, Cu, Co, Fe and Mo that were above screening values. Concentrate tailings and whole tailings also showed infrequent concentrations of Cd and Cr that were above screening values. Lead was above screening in one sample of concentrate. Silver and U were above screening values in whole tailings (one sample and three samples, respectively). Mercury concentrations were below PWQO screening values in all samples.
- SFE results for desulphurized tailings, concentrate tailings and whole tailings showed most metals were below PWQO screening values and those concentrations were notably lower than supernatant concentrations. All samples of desulphurized tailings and whole tailings had Hg SFE concentrations below the screening values.

Table 6.2-1: Summary of Synthetic Tailings Samples

Sample Type	Number of Samples	
	Zone	Description
Desulphurized tailings	LP Zone	7 tailings samples (post-CND)
Concentrate tailings	LP Zone	9 tailings samples (post-CND)
Whole tailings	LP Zone	6 tailings samples [1]
	Hinge Zone	2 tailings samples [2]
	Limb Zone	1 tailings sample [3]

6.3 KINETIC TESTING

6.3.1 PROGRAM OVERVIEW

A kinetic testing program was undertaken to assess the metal leaching and acid generation potential of synthetic tailings samples produced as part of the Project metallurgical testing program, as well as prepared paste backfill material. This included the use of humidity cell tests and column tests for the tailings, as well as additional kinetic tests for the paste backfill. The purpose of these tests and key aspects of the program are described below.

Key aspects of the Project flowsheet are summarized in Section 6.2.2.

Tailings

The tailings kinetic testing program was initiated in 2023 and includes the following tests:

- Four humidity cells containing samples of desulphurized tailings (post-CND), which represent the bulk of tailings to be produced during the Project based on the current mine plan. Cells were initiated in two stages and available results include 22 to 55 weeks of data. The samples included in humidity cell tests were selected from a set of seven desulphurized tailings samples generated in metallurgical testing. Samples selected for humidity cell testing represented S, NP and metals content in the moderate to high range of values identified for desulphurized tailings (Appendix G). All four samples tested in humidity cells are representative of the LP Zone, from which the bulk of the Project tailings will be derived based on the current mine plan. This section contains data reported up to November 2024 for humidity cells containing desulphurized tailings.
- One subaqueous recirculating column test containing a sample of concentrate tailings (post-CND). Concentrate tailings are planned to be stored under water cover at the VMF. Twenty-two weeks of data is available for this test. The sample tested in the subaqueous column comprised a composite of all nine concentrate tailings samples that were produced during metallurgical test work. All concentrate tailings included in the subaqueous recirculating column are representative of the LP Zone. This section contains data reported up to November 2024 for the column test containing concentrate tailings.
- Five humidity cells containing samples of whole tailings (post-CND). Three of the samples represent the tailings that will be used to generate paste backfill for the underground workings. The other two samples represent tailings from low volume ore zones that are included for completeness. Eighty-three weeks of data are available. This section contains data reported up to December 2024 for humidity cells containing whole tailings.

The humidity cell tests are intended to provide the following information to support the Project:

- Rates of sulphide oxidation, depletion of neutralization capacity, and metal release.
- Interpreted timing of acid onset in PAG materials.
- Site-specific NPR thresholds to define PAG material, where applicable.

The objective of the column test is to evaluate mass load release from the submerged concentrate tailings.

Paste Backfill

In 2024, two kinetic tests were initiated with paste backfill prepared according to current Project engineering specifications. The tests included:

- One subaerial kinetic test, intended to provide information regarding the quality of water following contact with backfilled surfaces under subaerial conditions (e.g., throughout the operations phase of the Project, prior to flooding of the underground). The test was terminated in December 2024, and

25 weeks of data are available. This section contains all data reported up to the test's termination in December 2024.

- One subaqueous kinetic test, intended to provide information regarding the quality of water in contact with backfilled surfaces under submerged conditions (e.g., after the underground is filled with water at closure). This test was terminated in December 2024, and 22 weeks of data is available. This section contains all data reported up to the test's termination in December 2024.

These tests evaluated the geochemical characteristics of the material in terms of sulphide oxidation / metal release and water quality.

A summary of the tailings kinetic testing program is provided below in Table 6.3-1, including key geochemical information for the test samples. Additional kinetic test work is ongoing to evaluate the applicability of potential Project-specific thresholds to distinguish PAG and NPAG tailings.

Humidity Cell Testing Program

Humidity cell testing is underway on samples that represent the desulphurized tailings expected to be discharged to the TMF throughout operations. Humidity cell testing was also conducted on simulated samples of whole tailings that were prepared prior to the current Project flowsheet for tailings and represent the whole tailings that will be used to generate paste backfill for the underground workings.

All humidity cell tests operate at Global ARD in Burnaby, British Columbia following procedures presented in MEND (2009) and described in Section 4.4.1.

- The humidity cell tests were prepared with 1 kg of tailings and flushed weekly with 500 mL of deionized water. Leachates drained from the cells were analyzed as follows:
  - Weekly analysis of pH, EC and sulphate throughout the entire operating period of all humidity cells (HC-1 through HC-9).
  - For HC-1 through HC-6, acidity and alkalinity were analyzed weekly from week 0 to 23, and biweekly from week 25 onwards. For HC-7 through HC-9, acidity and alkalinity were analyzed weekly throughout the entire operating period.
  - Chloride and fluoride were monitored weekly from week 0 through week 23 for all humidity cells (HC-1 through HC-9). Results of monitoring were assessed throughout operation of the cells and the monitoring frequency was decreased and / or discontinued when measured concentrations in leachate were consistently below detection limits (HC-1 to HC-6). Chloride monitoring for HC-6 stopped in week 23 when fluoride analysis was discontinued and resumed in week 47 following review of available data.
  - Nitrogen species (nitrite, nitrate and total ammonia) and cyanide species (total cyanide, weak acid dissociable cyanide, free cyanide, total cyanate and thiocyanate) were monitored weekly from week 0 through week 11 for HC-1 through HC-6, and from week 0 through week 20 for HC-7 through HC-9. Results of monitoring were assessed throughout operation of the cells and the monitoring frequency was decreased to biweekly and / or discontinued when measured concentrations in leachate were consistently below detection limits.
  - Dissolved P by colourimetry, Hg by CVAA and dissolved metals by ICP-MS (Al, Sb, As, Ba, Be, Bi, B, Cd, Cr, Co, Cu, Fe, Pb, Li, Mn, Mo, Ni, Se, Si, Ag, Sr, Tl, Th, Sn, Ti, W, U, V, Zn, Zr, K, Na, Ca, and Mg) were analyzed weekly from week 0 to 23 and biweekly from week 25 onwards for humidity cells HC-1 through HC-6. Dissolved metals were analyzed weekly for humidity cells HC-7 to HC-9.
- Leachate chemistry was used to calculate release rates. Release rates were calculated based on the mass of the tailings sample used in the test for the purposes of this assessment.
- Calculated release rates were used to determine trends in metal release, the rates of sulphide oxidation and neutralization potential depletion, and to estimate the lag time to acid onset in the samples, where applicable.

Concentrate Tailings Subaqueous Recirculating Column Testing

Column testing is underway for one sample of simulated concentrate tailings representative of the tailings to be discharged throughout operations. Concentrate tailings will be stored under water cover in the VMF. The subaqueous recirculating column operates at the Global ARD laboratory in Burnaby, British Columbia.

The test includes a sample of concentrate tailings maintained under a recirculating water cover in a clear acrylic column (see Section 4.4.3 for a conceptual drawing). The test is operated following the procedures described in Section 4.4.3.

Leachates were analyzed as follows:

- Leachate collected from the sampling tube located at the tailings - water interface was analyzed weekly for DO and ORP throughout the entire operating period of the test.
- Leachate collected from the sampling tube located 14 cm above the tailings - water was analyzed for pH, EC, acidity, alkalinity, sulphate, chloride, fluoride, dissolved P by colourimetry, hardness, Hg by CVAA, and dissolved metals by ICP-MS (Al, Sb, As, Ba, Be, Bi, B, Cd, Cr, Co, Cu, Fe, Pb, Li, Mn, Mo, Ni, Se, Si, Ag, Sr, Tl, Th, Sn, Ti, W, U, V, Zn, Zr, K, Na, Ca, Mg and S). Analysis was conducted weekly throughout the entire test period for all parameters except for nitrogen species (nitrite, nitrate and ammonia) and cyanide species (total cyanide and WAD cyanide), which was decreased to biweekly monitoring after nine weeks of testing.
- Leachate chemistry was used to calculate release rates. Release rates were represented as a flux (e.g., release rate per planar surface area of tailings in contact with the overlying water column).
- Calculated release rates were used to assess trends in metal release from the concentrate tailings under submerged conditions.

Subaerial Paste Backfill Kinetic Test

The subaerial backfill kinetic test comprised a slab of backfill placed on an angle in a plexiglass container. Water was percolated onto the angled backfill surface and allowed to flow down the slab surface before being collected in a vessel at the bottom of the angled slab. Details are provided in Section 4.4.4.

The test was operated at the Global ARD laboratory in Burnaby, British Columbia for 25 weeks, and was terminated in December 2024 after monitored parameters were observed to stabilize or be on decreasing trends. Specifications of test setup are presented in Section 4.4.4.

- Leachate was analyzed for pH, EC, acidity, alkalinity, ORP, DO, sulphate, chloride, fluoride, nitrite, nitrate, total ammonia, total cyanide, WAD cyanide and P (by colourimetry), Hg (CVAA), and dissolved metals by ICP-MS (Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mn, Mo, Na, Ni, Pb, Sb, Se, Sr, Ti, Tl, U, V, W, Zn and Zr).
- Leachate chemistry was used to calculate release rates. Release rates were based on the surface area of the backfill slab in contact with the deionized water.

Subaqueous Paste Backfill Kinetic Test

The subaqueous backfill test comprised cast spheres of prepared backfill maintained under a recirculating water cover in a Plexiglas column. The test was operated at the Global ARD laboratory in Burnaby, British Columbia for 22 weeks, and was terminated in December 2024 after monitored parameters had stabilized. Prior to the 22 week testing duration, nine pre-leaching cycles were completed in which each cycle used approximately 2 L of deionized water to saturate and then rinse the backfill spheres. Details of the testing is provided in Section 4.4.5.

- Leachate was analyzed for pH, EC, acidity, alkalinity, ORP, DO, sulphate, chloride, fluoride, nitrite, nitrate, total ammonia, total cyanide, WAD cyanide and P (by colourimetry), Hg (CVAA), and dissolved metals by ICP-MS (Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mn, Mo, Na, Ni, Pb, Sb, Se, Sr, Ti, Tl, U, V, W, Zn and Zr).

- Leachate chemistry was used to calculate release rates. Release rates were represented as a flux (e.g., release rate per surface area of paste backfill in contact with the overlying water column).

6.3.2 QUALITY ASSURANCE AND QUALITY CONTROL

Kinetic test data was validated through review of charge balance anomalous data spikes if applicable and comparison of ICP S and sulphate S in kinetic test leachate.

No QA / QC issues were noted in the kinetic testing programs.

6.3.3 DESULPHURIZED TAILINGS

Four humidity cells comprising desulphurized tailings representative of the LP Zone and the current mine plan were initiated in 2024 (HC-6 through HC-9). Full static testing results for the samples included in the kinetic testing program are included in Appendix G.

Humidity cell test results are presented in Appendix H and contain data reported up to November 2024. Key observations over the first 55 weeks of testing for HC-6, and the first 22 weeks of testing for HC-7, HC-8 and HC-9 are summarized below:

- The leachate pH for all desulphurized tailings cells (HC-6 through HC-9) ranged from approximately pH 6 to 7 (Figure H-1) over the test period. Leachates were generally stable around pH 6.5 to 7 in recent data.
- Sulphate release rates decreased for all cells since the start of testing to values between 20 to 30 mg/kg/week after 22 weeks of testing. Cell HC-6 continued to steadily decline to approximately 7 mg/kg/week after 55 weeks of testing (Figure H-4).
- Arsenic release rates showed a steady to steadily decreasing trend over the test period and were on the order of 0.0001 to 0.004 mg/kg/week in recent data (Figure H-8). A relationship of higher As release with higher molar ratios of As to S was observed, (Figure 6.3-1 below).
  - Notably, cell HC-8 had a similar solid phase As content as cell HC-7 but had As release rates that were an order of magnitude higher than As released by cell HC-7. Similar to observations made for supernatant, the HC-8 sample had a higher solid phase As:S molar ratio than all other desulphurized tailings samples included in the humidity cell testing program, indicating the As host mineralogy of HC-8 may influence As release and the sample may contain cobaltite-gersdorffite. Bulk mineralogical analysis by R-XRD did not identify any As mineral phases, potentially due to the low overall sulphide content of the desulphurized tailings.
  - A detailed mineralogical test program is underway to verify mineralogy of the test samples.
- Cadmium release rates for cells HC-6, HC-7 and HC-9 were based on concentrations in leachate below or near the detection limit. The Cd release rate of HC-8 fluctuated and was usually slightly higher relative to the other desulphurized tailings cells, which was attributed to the higher solid phase Cd content of the sample (Figure H-10).
- Molybdenum release rates for the desulphurized tailings cells (HC-6 through HC-9) fluctuated throughout testing; three of the four cells (HC-6, HC-7, HC-9) showed increasing release rates after approximately 10 to 30 weeks of testing to approximately 0.002 mg/kg/week in the last week of data (Figure H-11).
- Cobalt release rates decreased throughout testing to approximately 0.0001 mg/kg/week (cells HC-7, HC-8, HC-9) and 0.0006 mg/kg/week (HC-6; Figure H-18).
- Copper release rates decreased throughout testing to approximately 0.002 mg/kg/week in recent weeks (Figure H-19).
- Iron release rates for HC-7, HC-8 and HC-9 range from 0.005 to 0.01 mg/kg/week in recent data Figure H-20). The Fe release rate for HC-6 (the longest running humidity cell containing desulphurized tailings) increased over the last 35 weeks of testing, with recent data on the order of

0.05 mg/kg/week (Figure H-20). The cell had a leachate pH between 6 and 7 and a similar trend in WAD cyanide release, suggesting that Fe release is associated with dissolution of Fe-cyanide phases.

- Concentrations of several parameters including Be, Be, Cr, Pb, Hg, Ni, Ag, V and Zn were generally at or near the analytical detection limit for the duration of testing.
- Release rates for total cyanide and WAD cyanide showed an increasing trend in cell HC-6 after 25 weeks of testing, with release rates on the order of 0.2 mg/kg/week and 0.01 mg/kg/week respectively (Figures H-38 and H-39). Cells HC-7 and HC-8 also showed increasing release rates after approximately 5 weeks of testing, though release rates remained low in available data after 22 weeks of testing. Notably, these samples did not achieve targeted cyanide levels during testing of the CND process which necessitated precipitation of Fe-cyanide phase(s) from solution as part of metallurgical testing. This information, combined with the observed concurrent increase in Fe leaching suggests that dissolution of a precipitated cyanide-bearing phase or phases may be occurring. Great Bear Resources continues to refine the cyanide destruct process using SO_2 / air and precipitation of similar quantities of cyanide bearing phases is not expected under operational conditions.

Lag Time to Acid Onset

The pH of leachate from all desulphurized tailings humidity cells remained between 6 and 7 throughout the entire testing period. The time to depletion of sulphide and neutralization potential in the humidity cells was estimated to verify the ARD classification of desulphurized tailings. Estimated lag times are presented in Table 6.3-2 based on the available data.

- It was assumed that all the sulphate released in the humidity cells was due to sulphide oxidation and thus resulted in the dissolution of neutralization potential within the sample.
- For the purposes of this assessment, it was assumed that rates of sulphide oxidation in the humidity cells were representative of sulphide oxidation rates for tailings in the field; however, in northern environments field oxidation rates are generally slower than laboratory measured rates due to lower temperatures during the winter months which slow chemical reaction rates (MEND 2006) and can extend lag times. This will be further evaluated as part of geochemical programs for the Project.
- Sulphur release rates were determined based on the median sulphate release rate measured over the last five weeks of testing. Sulphur release rates were then used to calculate AP release rates. NP loss rates were calculated based on the median of the combined Ca and Mg release rates measured through the last five weeks of testing in cells where the CMR was less than two in the last five weeks of testing (e.g., HC-7 through HC-9). The CMR of HC-6 was above two in the last five weeks of testing, and NP loss rates were therefore calculated assuming a 1:2 ratio of AP release rates and NP dissolution.
- CarbNP was used as the measure of available acid neutralization capacity, except for cell HC-5 which had a higher CarbNP than Modified NP and Modified NP was therefore used for this cell.

Depletion estimates indicated that sulphide depletion will occur prior to NP depletion and identified no potential for net acidic leachates from the desulphurized tailings samples (HC-6 through HC-9).

This was consistent with the classification of desulphurized tailings as NPAG based on ABA test data.

Metal Release

In general, release rates from the desulphurized tailings humidity cells (HC-6 through HC-9) were relatively low for most metals, with relationships noted between release rates and solid phase concentrations for several parameters including Cd and As particularly when As:S ratios were considered. Release rates for several parameters including Be, B, Cr, Pb, Hg, Ni, Ag, V and Zn were based on concentrations in leachate that were below analytical detection limits throughout most of the testing period.

An increase in cyanide leaching was noted, with a similar increasing trend in Fe release noted over the same time period. The metallurgical process has been modified to include an aeration stage to remove

Fe prior to CND, which is expected to result in less solid cyanide phases being precipitated. Additional metallurgical testing is underway.

6.3.4 CONCENTRATE TAILINGS

One subaqueous recirculating column test was initiated using a composited concentrate tailings sample in June 2024 (sample name COMP-S; test reference COL-1). As previously described, the subaqueous recirculating column test maintains a water cover over the concentrate tailings that is slowly and continuously circulated.

On a weekly basis, a leachate sample is removed from the overlying water column, removing load from the system and replacing it with an equal volume of fresh deionized water. The load lost through the preceding week's sampling event was determined and (mathematically) added to the calculated load remaining in the column. Since the test is operated as a recirculating column (e.g., load is retained in the overlying water each week), weekly release rates were calculated based on the change in load in the column from week to week. Release rates are therefore presented as a flux (e.g., load per planar surface area of tailings in contact with the overlying water: mg/m^2/week) in Appendix I (Figures I-1 through I-41). Where the change in load released from the sample was negative (e.g., load was lost during sampling) or equal to zero, release rates were determined based on one-half of the detection limit value for the given parameter. For completeness, leachate sample concentrations are also included in Figures I-1 to I-41.

Results are presented in Appendix I which contains data reported up to November 2024. Key observations over the first 22 weeks of testing are summarized below:

- The pH of column water decreased in the first five weeks of testing to a minimum value of pH 5.7 likely due to minor sulphide oxidation, as evidenced by concurrent sulphate release over this period and decreasing dissolved oxygen levels (Appendix I; Figures I-1, I-7 and I-4). After the first five weeks of testing, pH increased steadily to approximately pH 6.5 in recent data and sulphate release rates were considerably lower than in the first five weeks of testing.
- Dissolved oxygen, measured in column at the tailings - water interface, decreased over the first six weeks of testing, then slowly returned to oxygen levels that were similar to the start of testing (Figure I-4). Patterns in dissolved oxygen concentrations suggested higher levels of oxygen consumption early during testing, consistent with low levels of sulphide oxidation occurring at the surface of the tailings. Sulphide oxidation rates were low under subaqueous conditions and decreased throughout the test as evidenced by low and decreasing sulphate release rates.
- Cyanide species showed positive net load release and an increasing trend in column concentrations (Figure I-14 and I-15). This was attributed to slow release of residual pore water from the sample, rather than the dissolution of solid phase Fe cyanides, as no concurrent increase in Fe release was observed.
- Metal release rates in the concentrate tailings column were low overall, consistent with the subaqueous condition of the test and low sulphide oxidation rates. Release rates decreased throughout testing and were based on detection limit values
- in at least one of the last five weeks of testing for all reported parameters. The majority of data showed concentrations below the analytical detection limits for Al, Sb, Be, Bi, B, Cr, Pb, Li, Ni, Tl, Th, Ti, W, V and Zr.

Lag Time to Acid Onset

Lag times to acidification were not determined for the concentrate tailings under subaerial conditions, as it is assumed that this would occur in a very short timeframe. For Project purposes, the concentrate tailings will be managed in a saturated condition under a water cover in the VMF. Results of the column test demonstrated low rates of sulphide oxidation and metal release from the concentrate tailings under subaqueous condition.

Metal Release

Metal release rates for the concentrate tailings sample (COL-1) were low and showed lower release rates in the last weeks of testing, with many parameters (including Sb, Be, Cr, Pb, Mo, Ni, Ag, Tl, W, V, Zn and Zr) below analytical detection limits in recent weeks data. Total cyanide and WAD cyanide release rates were relatively low throughout the available data, attributed to the slow release of pore water from the tailings sample.

6.3.5 WHOLE TAILINGS

Five humidity cell tests were initiated on samples of synthetic whole tailings (HC-1 through HC-5) in May 2023. These samples represent tailings from the LP Zone, which represents the bulk of the ore feed for the Project. Tailings samples from two smaller ore zones, the Limb Zone and Hinge Zone, were also included.

The tailings represent whole tailings that will be used to generate paste backfill. Static testing results for the samples included in kinetic testing are presented in Appendix G.

Results are presented in Figures J-1 to J-42 of Appendix J which contains data reported up to December 2024. Key observations from humidity cell testing on whole tailings samples are summarized below:

- The pH of all cells has ranged between 6 and 7 throughout testing (Figure J-1).
- Sulphate release rates generally stabilized after 70 weeks, with release rates on the order of 20 to 50 mg/kg/week (HC-1 to HC-4; Figure J-4). Sulphate release rates for HC-5 (Limb Zone) showed a slowly increasing trend throughout the test, with release rates on the order of 100 mg/kg/week since approximately week 50.
- Arsenic release rates were on the order of 0.00005 to 0.002 mg/kg/week and showed relatively stable to decreasing trends in recent data. As previously noted, the higher As:S molar ratio content of humidity cell samples generally corresponded to higher As release rates (Figure 6.3-1). The highest As release rates were observed for the Limb sample (HC-5, approximately 1500 mg/kg As) and two of the LP samples (HC-1 and HC-3, approximately 200 mg/kg As; Figure J-8).
- Cadmium release rates for HC-2 (LP Zone) and HC-5 (Limb Zone) were elevated compared to the other whole tailings cells which were attributed to higher solid phase Cd concentrations in these test samples (0.52 mg/kg and 1.2 mg/kg respectively). Both cells showed a slight increasing trend over the last 10 weeks of testing to release rates on the order of 0.00006 mg/kg/week (HC-2) and 0.00002 mg/kg/week (HC-5). Cd release for HC-1 (LP Zone), HC-3 (LP Zone) and HC-4 (Hinge Zone) remained stable at approximately 0.000004 mg/kg/week (Figure J-10) and were based on Cd concentrations that were below the detection limit.
- Molybdenum release rates for HC-1(LP Zone), HC-2 (LP Zone), HC-4 (Hinge Zone) and HC-5 (Limb Zone) stabilized after 30 weeks of testing to rates between 0.0004 and 0.0005 mg/kg/week (Figure J-11). Molybdenum release rates for HC-3 (LP Zone) varied by an order of magnitude throughout the test period and showed periods of broadly increasing and decreasing release rates. After week 60, release rates increased to approximately 0.006 mg/kg/week in week 83 for this cell (Figure J-11). The elevated Mo release rates observed for HC-3 were attributed to the higher solid phase Mo content in this cell (5.4 mg/kg).
- Cobalt release rates were steady and ranged from 0.0001 to 0.001 mg/kg/week (Figure J-18).
- Selenium release rates were low and ranged from 0.0001 to 0.0005 mg/kg/week (Figure J-9).
- Mercury concentrations were very low throughout testing and were generally below the analytical detection limit (0.0000019 mg/L) in all whole tailings tests (HC-1 through HC-5; Figure J-22).
- Cyanide species release rates were steady and did not follow the pattern of increasing cyanide release that was observed in the desulphurized tailings and tailings concentrate.

Lag Time to Acid Onset

The time to depletion of sulphide and neutralization potential in the humidity cells was estimated to provide guidance on the time to acid onset for PAG tailings. Estimated lag times are presented in Table 6.3-2. For the purposes of this assessment, the following assumptions and approaches were used:

- It was assumed that all the sulphate released in the humidity cells was due to sulphide oxidation and thus resulted in the dissolution of neutralization potential within the sample.
- It was assumed that rates of sulphide oxidation in the humidity cells were representative of sulphide oxidation rates for tailings in the field; however, in northern environments field oxidation rates are generally slower than laboratory measured rates. Lower temperatures during the winter months may slow oxidation rates and extend the lag times. This will be further evaluated as part of geochemical programs for the Project.
- Sulphur release rates were determined based on the median sulphate release rate measured over the last five weeks of testing. Sulphur release rates were then used to calculate AP release rates. NP loss rates were calculated based on the median of the combined Ca and Mg release rates measured through the last five weeks of testing in cells where the CMR was less than two in the last five weeks of testing.
- CarbNP was used as the measure of available acid neutralization capacity in the samples. Calculations for one sample (HC-5) utilized Modified NP as the data indicated the potential presence of an excess of non-neutralizing carbonate minerals.

Key findings are as follows:

- Depletion estimates indicated that the three LP Zone whole tailings samples (HC-1, HC-2 and HC-3) were PAG with lag times to acid onset estimated to be on the order of 3 to 14 years (Table 6.3-2).
- One whole tailings sample (HC-5, Limb Zone) that was classified as PAG by ABA testing (CarbNPR=1.3) is considered NPAG using humidity cell testing as a result of high sulphate release rates and a short calculated sulphide depletion time compared to CarbNP depletion times. However, it is noted that the calculated time to CarbNP depletion and sulphide depletion are similar and small changes in release rates could affect the classification of the sample. Further, the characteristics of the Limb Zone sample (e.g., 4% S and 152 kg $CaCO_3$/t CarbNP) do not represent the overall Project tailings and results of this test are not suitable to define a site-specific NPR for the tailings.
- The Hinge Zone whole tailings sample (HC-4) is classified as NPAG, which is consistent with ABA test data.

Metal Release

Metal release rates for the whole tailings humidity cells (HC-1 through HC-5) were generally slightly higher than release rates determined for the desulphurized tailings samples but remained relatively low, with concentrations of many parameters (including Hg) consistently below analytical detection limits throughout testing. As with the desulphurized tailings, trends were noted between solid phase content of As and Cd and release rates for these parameters.

6.3.6 PASTE BACKFILL SUBAERIAL KINETIC TEST

Subaerial kinetic testing of backfill was initiated in July 2024 using prepared paste backfill. The subaerial test was terminated in December 2024 after 25 weeks of testing as monitored parameters had generally stabilized. Static testing results for the prepared paste backfill used in kinetic testing are included in Appendix G.

Results of the subaerial kinetic test are presented in Figures K-1 to K-42 of Appendix K which contains data reported up to December 2024. Key observations throughout the 25 weeks of operation are included below:

- Leachate pH (Figure K-1) showed a steady and slightly increasing trend over the duration of testing, from approximately pH 6 at start-up to approximately pH 7 after 25 weeks of testing. Acidity concentrations ranged between 14 and 50 mg $CaCO_3$/L and showed an overall decrease throughout testing (Figure K-5). Alkalinity concentrations ranged from 15 and 30 mg $CaCO_3$/L and showed a relatively steady to decreasing trend.
- Sulphate concentrations were on the order of 250 to 500 mg/L during the first 5 weeks of testing and then steadily decreased toward 100 mg/L after 25 weeks of testing (Figure K-7).
- Metal concentrations in leachate were low with many parameters (including Sb, Be, B, Cd, Cr, Pb, Hg, Ni, Ag, Tl, W, V, Zn, Zr) having reported concentrations that were below the analytical detection limit. Other parameters including Co, Cu, Fe, Mo and Se showed decreasing trends throughout the test.
- Mercury was below detection in most weeks of testing, with stable and detection-limit based Hg release in recent data.
- Results of kinetic testing suggest that some oxidation of the backfill slab is expected with low levels of concurrent metal release under subaerial conditions for a limited duration after placement. Backfilled stopes will be effectively sealed and low oxygen conditions will further limit oxidation in underground conditions prior to natural flooding that will occur at closure.

Lag Time to Acid Onset

The subaerial kinetic test cannot be used for calculation of lag times and lag times were therefore not determined for these materials. However, the AP and NP properties of the prepared backfill closely resembled those of the whole tailings materials used in preparation of the paste backfill. Similar whole tailings samples tested in humidity cells (HC-1 and HC-3) indicated a lag time of on the order of 10 to 14 years under subaerial conditions.

Based on trends in the release rates for the whole tailings, and the NP and AP content of the paste backfill, a lag time for the paste backfill is currently estimated to be on the order of 10 years under laboratory conditions. However, placement of the paste backfill underground in cooler (approximately 10°C) conditions and in sealed stopes that will limit interaction with oxygen and water is expected to prolong the above estimated laboratory lag time. Humidity cell tests have been initiated with paste backfill samples.

Metal Release

Metals concentrations in leachate from the paste backfill subaerial kinetic test were low and stable, with several parameters consistently below detection limits including Sb, Be, B, Cd, Cr, Pb, Hg, Ni, Ag, Tl, W, V, Zn and Zr.

6.3.7 SUBAQUEOUS RECIRCULATING COLUMN TEST

A subaqueous recirculating column test was initiated in July 2024 using prepared paste backfill. Static testing results for the prepared paste backfill used in kinetic testing are included in Appendix G.

On a weekly basis, a leachate sample was removed from the overlying water column, removing load from the system and replacing it with an equal volume of fresh deionized water. The load lost through the preceding week's sampling event was determined and (mathematically) added to the calculated load remaining in the column. Since the test was operated as a recirculating column (e.g., load is retained in the overlying water each week), weekly release rates were calculated based on the change in load in the column from week to week. Release rates are therefore presented as a flux (e.g., load per planar surface area of tailings in contact with the overlying water, mg/m^2/week) on Figures L-1 through L-42 in Appendix L which contains data reported up to the test's termination in December 2024.

Where the change in load released from the sample was negative (e.g., load was lost during sampling) or equal to zero, a base load minimum release rate was calculated using one-half of the detection limit value

for the given parameter. For completeness, leachate sample concentrations are also included in Appendix L (Figures L-1 to L-42).

The subaqueous recirculating column test was terminated in December 2024 after 22 weeks as monitored parameters had stabilized or showed decreasing trends.

During the nine pre-leach cycles of flooding and draining the column, pH, sulphate and metals concentrations were measured and compared to the water quality observed for the subaerial backfill test. pH values were higher (pH 7 to pH 8) compared to the subaerial backfill test and sulphate and metals concentrations were either similar to the concentrations in subaerial leachate in all cycles (Sb, Cd, Pb, Hg, Zn and Zr) or similar initially then lower after two to three flushing cycles (Co, Cu, Fe, Se, Sr; Appendix L).

Key observations through the 22 weeks of operation for the subaqueous recirculating column test are summarized below:

- The pH of leachate from the subaqueous recirculating column test increased slightly throughout testing from 6.2 at the onset of testing to 7.1 after 22 weeks of operation (Figure L-1).
- Acidity release rates were low (median 5 mg/m^2/week) throughout the test (Figure L-5) and usually based on minimum loading rates [13] (e.g., detection limit multiplied by water volume).
- Alkalinity (Figure L-6) was detected throughout the test, with recent release rates (around 100 mg/m²/week) remaining close to initial values (150 mg/m²/week).
- Sulphate release rates were low and variable throughout testing, with a median sulphate release rate of 26 mg/m^2/week (ranging from approximately 5 mg/m^2/week to 250 mg/m^2/week; Figure L-7). Sulphate release rates in the subaqueous recirculating column were one to two orders of magnitude less than release rates observed for paste backfill under subaerial conditions.
- Metal release was low and generally stable to decreasing in the submerged backfill. Release for several key parameters were usually based on base load minimum release rates (see footnote), including As, Sb, Be, Cr, Cu, Fe, Pb, Hg, Ni, Se, Ag, Tl, W, U, V, Zn and Zr and were generally lower than release rates in the subaerial kinetic test. These low release rates may be higher than expected in field conditions due to observations made in the laboratory that approximately half of the cast spheres broke in half and further disintegrated throughout the test, likely resulting in higher loads than if the material had stayed intact.

Metal Release

Metal release rates in the paste backfill subaqueous kinetic test were generally lower than release rates in the subaerial kinetic test as expected. Release for several key parameters were generally stable and based on base load minimum release rates (see footnote), including As, Sb, Be, Cr, Cu, Fe, Pb, Hg, Ni, Se, Ag, Tl, W, U, V, Zn and Zr.

Lag Time to Acid Onset

The subaqueous recirculating column test cannot be used for calculation of lag times and lag times were therefore not determined for these materials. However, paste backfill is not at risk for acid generation under subaqueous conditions due to low oxygen levels.

[13] Where the change in load released from the sample was negative (e.g., load was lost during sampling) or equal to zero, a base load minimum release rate was calculated using one-half of the detection limit value for the given parameter.

6.3.8 KEY FINDINGS

Key findings for each material type are discussed below. Lag time information is presented above for each material type and summarized in Table 6.3-2 below. Summarized release rates are presented in Table 6.3-3 for selected parameters.

Desulphurized Tailings

- Results of humidity cell testing conducted on the desulphurized tailings samples (HC-6 through HC-9) indicated no potential for net acidic leachates, and low metal release rates. Metal release rates were generally lower for desulphurized tailings than whole tailings, as expected, with the exception of Cu which was slightly higher in the desulphurized samples compared to whole tailings, likely due to the addition of $CuSO_4$ in the flotation and CND circuits.
- Mercury concentrations in test leachates were very low throughout testing and were below the analytical detection limit in most samples.

Concentrate Tailings

- Results of the subaqueous recirculating column test on the concentrate tailings indicated that oxidation of the sample was limited under submerged conditions. Minor sulphide oxidation early in the test was evidenced by concurrent sulphate release and decreasing dissolved oxygen levels and pH in the first five weeks. After that time, sulphate release rates decreased, and pH and dissolved oxygen levels increased, which indicated that oxidation was limited in extent. Metal release rates were low throughout testing and stabilized in the last five weeks of testing for most parameters. Detailed mineralogy testing has been initiated on a representative split of the column sample.

Whole Tailings

- Results of humidity cell testing conducted on whole tailings indicated that three of the samples (representing the LP Zone) were potentially acid generating with lag times to acid onset estimated to be on the order of 3 to 14 years. The remaining two samples of whole tailings tested representing the Limb and Hinge Zones were determined to be NPAG by kinetic testing. Metal release rates were low throughout testing, and Hg concentrations were usually below the analytical detection limit.

Paste Backfill

- Results of kinetic testing conducted on paste backfill generally indicated low metal release from both the subaerial and subaqueous tests. Release rates from the subaqueous kinetic test, representing submerged backfill under closure conditions, were generally lower than release rates observed from the subaerial test. Mercury release rates were low throughout testing and were below detection in every week of the subaqueous kinetic test, and below detection in the last 19 weeks of the subaerial test. Release rates of other key parameters (e.g., As and Co) were low with stable to decreasing trends observed throughout testing.
- The prepared backfill samples had similar geochemistry to the whole tailings (used to prepare the backfill), which had a lag time estimate of approximately a decade. However, prepared backfill is expected to have a longer lag time to net acidic conditions when placed in sealed underground stopes due to cooler temperatures and materially reduced airflow during operations and ultimately under submerged conditions at closure.

Table 6.3-1: Data Summary for Samples Included in Kinetic Testing Program

Test ID	Sample ID	Sample Description	Zone	Initiation Date	Weeks Operating	Total S [1] (%)	MPA [2] (kg $CaCO_3$/t)	CarbNP [3] (kg $CaCO_3$/t)	NP [4] (kg $CaCO_3$/t)	CarbNPR [5] (CarbNP/ MPA)	NPR [6] (NP/AP)

Notes

1 *Release rates based on median release rates for the last five weeks of data. AP release rates based on sulphate release rates. NP release rates based on measured NP loss (as Ca and Mg) for cells with CMR <2; for cells with CMR >2, NP release rate was estimated from AP release rates, assuming a 1:2 ratio of acid potential production and neutralization potential dissolution.*

2 *Time to AP depletion based on MPA for all cells. Time to NP depletion based on carbonate NP except for HC-5, which used Modified NP, as CarbNP was greater than NP in this cell. Lag times include consideration for S and NP release during the entire test period, and the projected release of S and NP based on the release rates.*

3 *Neutralization potential ratio based on CarbNPR (CarbNP/MPA), except for HC-5 which was based on NPR (NP/MPA), as the sample appeared to contain non-net neutralizing carbonate minerals.*

4 *Estimated times to depletion for MPA and CarbNP are similar and small changes in release rates could affect the characterization of the sample. Characteristics of the Limb sample (e.g., 4% S and 152 kg CaCO3/t CarbNP) do not represent the overall Project tailings and results of this test are not suitable to define a site-specific NPR for tailings.*

7 OVERBURDEN

7.1 SUMMARY

A geochemical characterization program was undertaken to assess overburden materials that will be relocated as part of Project development. As part of the program, a total of 172 samples were submitted for static testing analyses, and 14 samples were included in laboratory-based trickle-leach column tests, which have 8 to 47 weeks of data currently available. The scope of the overburden characterization program conducted for the Project exceeds standard approaches for overburden materials for similar mining projects undergoing the approvals process in Ontario.

Geochemical testing on 172 samples of overburden indicated that the overburden is NPAG based on an average CarbNPR of 37. The samples had a very low total S content; total S was below the analytical detection limit in approximately 30% of the samples. Where detectable, total S concentrations ranged from 0.006% to 0.11% (median 0.01%).

Ninety-six percent of the samples (i.e., n=165) had a CarbNPR >2 and were considered NPAG. Seven samples had a CarbNPR ≤2 and generally consisted of glacial sands with no neutralization capacity and S contents that were at or very close to the detection limit. These materials are not considered a risk for acid generation. This was consistent with NAG test results that indicated that these samples were NPAG.

Most samples had a Modified NP content on the order of 8 kg $CaCO_3$/t, although it ranged from -0.7 to 135 kg $CaCO_3$/t (Appendix M1). NP was predominantly represented by CarbNP for most samples; however, samples with a low Modified NP content often contained no CarbNP. Samples that comprised glacial sand most often had low levels of NP, likely reflecting the predominance of quartz in these samples.

The samples had a low solid phase metals content that were usually below screening values. Solid phase mercury concentrations were below the analytical detection limit for most samples and below screening values for all samples.

SFE testing showed concentrations of metals in leachates that were generally below screening values in most samples with the exception of Ag, Cr and Cu in approximately 15% of samples and concentrations of As, Co, W, U, V and Zr, in isolated samples. Overall, however, metal concentrations were generally low. Mercury concentrations in SFE leachates were below analytical detection limits for 96% (n=121) of the samples and below screening values for all samples. Results from the SFE tests do not represent drainage quality, but act as a screening tool to identify parameters of potential interest.

It is noted that static testing (Section 7.2) demonstrated that the overburden samples were NPAG with very low S contents (typically below analytical detection limits) and low solid phase metal contents. Typically, materials with very low sulphide and metal contents below screening values are considered a low risk for ML / ARD and are not subject to kinetic testing; kinetic tests usually focus on material with a higher S or metal content considered to pose a potential risk. Despite this, the Project utilized a proactive and protective approach and included kinetic testing on overburden for completeness. Overburden laboratory kinetic testing utilized trickle leach column tests. The column tests were initiated between May 2024 and May 2025 and currently have 8 to 47 weeks of results available.

The pH of leachate from 13 of the 14 overburden column tests was generally stable between 6 and 8 throughout testing. Median sulphate and metal concentrations in leachate over the last five weeks of testing were low, and usually similar to or lower than those observed in baseline surface water data for the site, with many parameters (including Hg) consistently below analytical detection limits.

Column testing included three low NP samples with a range of S contents (<0.01 to 0.05%) that were collected from the near surface. Owing to their low NP content, these samples had an NPR ≤2; however, NAG pH testing indicated the samples were NPAG. Two of these three samples had column leachate pH values that were consistent with the other column tests (i.e., pH 6 to 8), including other tests that had a

lower NP content. Leachate pH for one sample (COL-3) was notably consistent with the blank columns. This was attributed to the pH of deionized water used in the laboratory test, as well as the low NP of the sample and the potential influence of natural organic acids that may have been present as the sample was collected near the soil interface. The sample had a very low sulphur content overall (0.03%) and leachate sulphate concentrations were low, indicating that sulphide oxidation was not driving the pH response of this test. Similar drainage quality is not anticipated to occur under field conditions, as testing indicates that in contrast to the COL-3 sample, most overburden materials produce alkalinity which provides buffering capacity to the drainage.

Construction of field kinetic tests is underway to further assess drainage quality under field conditions.

7.2 STATIC TESTING

7.2.1 PROGRAM OVERVIEW

A static testing program was undertaken to assess the geochemical characteristics of overburden materials that will be relocated as part of Project development. As part of the program, a total of 172 samples representing the various types of Project overburden were collected.

Samples underwent static testing which included: ABA analyses, NAG testing, elemental content analysis, SFE testing and bulk mineralogical analysis (by R-XRD). Results were reviewed to assess the metal leaching and acid generation potential of overburden materials. Kinetic testing was also conducted as outlined in Section 7.3.

The approach and testing methods utilized herein are based on the requirements described under the *Ontario Mining Act*; namely guidance found within the reference document *Prediction for Drainage Chemistry for Sulphidic Geologic Materials* (MEND 2009), which represents best practice and industry-standard approaches and methodologies for ML / ARD sampling and characterization in Canada.

7.2.2 SUMMARY OF AVAILABLE SAMPLES

A total of 172 overburden samples were collected between 2023 and 2025 as part of drilling and test pitting programs completed for the Project, including the following:

- Thirty samples collected in 2023 as part of the initial site-wide overburden characterization study undertaken for the Project.
- Eighty-six samples collected in 2024 to supplement the initial overburden characterization.
- Fifty-six samples collected in 2025 to further supplement the existing overburden database. This includes six large scale (3 to 4 m^3) samples that were collected from the open pit LP Central pit and AEX Program areas to be used in field leach tests. These samples were homogenized in the field and triplicate subsamples of the homogenized material were collected from each of the field test pad samples.

Samples were collected across the anticipated Project as shown in Figure 7.2-1 and summarized in Table 7.2-1.

Samples were selected based on the available test pits / drill holes advanced as part of hydrogeological and geotechnical investigations. Overburden at the Project typically ranges from 1 to 20 m and averages 10 m. Samples were selected to represent materials from surface to depths of up to 26.2 m below ground surface. Samples within several metres of the bedrock-overburden interface were also included in areas where deeper surface excavation will be required for mine development.

Samples included in this assessment represent the range of material types observed at the Project, including glacial till along with glaciofluvial and glaciolacustrine sediments. The glaciolacustrine sediments comprise three defined units as summarized in Table 7.2-2.

Detailed sample descriptions are provided in Table M-1 of Appendix M.

7.2.3 ANALYTICAL TEST METHODS AND SCREENING APPROACH

Static testing for the 30 samples collected in 2023 was conducted at SGS Lakefield. Static testing for the 142 samples collected in 2024 and 2025 was conducted at Global ARD. Consistent analytical methods were specified to be used by both labs to facilitate comparison of results and a complete dataset. Methods are briefly summarized below and presented in Section 4.3.

Prior to testing, all samples were passed through a 6.35 mm sieve to remove organic debris and any coarse gravel or cobbles. Subsequent sample preparation and testing was completed on the sieved portion of the sample.

Static testing methods are summarized in Table 7.2-3 and the approach used to screen the results for the metal leaching and acid generation potential of the samples are described below.

Following the initial test work, additional testing was undertaken for quality assurance and verification purposes. This additional test work is discussed further in Section 7.2.4.

- ABA testing was completed on all samples (n=172) to assess the potential for a sample to generate acidity, determined by the balance of acid generating and neutralizing minerals in a sample.
  - ABA testing included determination of paste pH, total S by Leco furnace, sulphate S by HCl leach, sulphide S by difference (total S – sulphate S), Modified NP [14], TC by Leco furnace, TIC by HCl leach and Leco furnace. CarbNP was calculated from TIC.
  - Acid generation capacity was calculated based on the results of S speciation testing, including the calculation of AP based on sulphide S, and MPA based on total S.
  - Test results were used to calculate the sample's NPR (NP/AP) and CarbNPR (CarbNP/MPA) to classify the acid generation potential of a sample. For Project planning purposes, ABA results with an NPR ≤2 were assumed to be PAG. Samples with an NPR >2 were considered to be NPAG (MEND 2009).
  - Triplicate subsamples from each of the large field leach test samples were tested in 2025. ABA results were found to be consistent between triplicate samples and results are presented as the average of the triplicate results for each field test sample.
- NAG testing was conducted on a subset of 100 samples to confirm the results of the ABA testing.
  - NAG pH results were screened against NAG pH criteria for PAG and NPAG materials (AMIRA 2002) and assessed in conjunction with NPR values from ABA testing.
  - NAG pH results for the triplicate subsamples collected from each of the large field leach test samples were consistent and were therefore presented as the average of the triplicate results for each field test sample.
- Elemental content analysis was conducted on all samples by aqua regia digest and ICP-MS scan. The purpose of this test is to assess the presence of environmentally meaningful elements and screen samples against qualitative threshold values. Results were screened against the following values for comparative purposes:
  - Ten times the average continental crust abundance of the given element (Price 1997). Samples with elemental concentrations greater than the qualitative screening value were considered enriched in those elements. The comparison to 10 times the crustal abundance value was made for screening purposes only and holds no regulatory significance.

[14] MEND 1991 method, based on the Lawrence 1989 Modified NP method.

  - Ontario Typical Range values for uncontaminated soils (MOE 2011). These comparisons were for screening purposes only and imply neither compliance nor non-compliance with soil quality standards as the overburden tested represent natural, background conditions.
  - Elemental content results were found to be reasonably consistent between the triplicate subsamples collected from each of the large field leach test samples, and results were therefore presented as the average of the triplicate subsamples.
- The potential release of soluble metals was assessed using the SFE test on a subset of 126 [15] samples, including each of the individual triplicate subsamples [16]. SFE results on the triplicate samples were not averaged as some parameters showed results that sometimes varied between the triplicate samples, which was attributed to subsample variability and / or analytical precision at low concentrations. The purpose of the test is to assess the presence of readily soluble metals and is not a direct indicator of drainage quality.
  - Leachates were analyzed for pH, conductivity, acidity, alkalinity, sulphate, total dissolved P by colourimetry, hardness and dissolved metals.
  - Leachate chemistry was compared to screening values to identify parameters of potential interest for metal leaching. The screening analysis included comparison of the SFE leachate chemistry to PWQO values for the protection of aquatic life, including both in-place PWQO values and interim PWQO values. The SFE test and screening approach is not a direct representation of future water quality and comparisons to screening criteria hold no regulatory significance.
- Mineralogical testing using R-XRD was conducted on 31 samples of Project overburden. Results for the triplicate subsamples for the large field leach test samples were consistent and results for these samples were therefore presented as an average.

7.2.4 QUALITY ASSURANCE AND QUALITY CONTROL

Static testing for 30 samples collected in 2023 was conducted at SGS Lakefield and static testing for the 142 samples analyzed in 2024 and 2025 was conducted at Global ARD. Upon receipt, data from both laboratories was reviewed for quality according to the methods outlined in Section 4.6.3. Where available, this included review of laboratory-provided QA / QC protocols such as replicates, duplicates and certified reference materials.

This review indicated that in general results of static analyses met the acceptability criteria described in Section 4.6.3. For most parameters, relative percent differences were found to be within acceptable limits (<10%) and were usually within 5% with rare exceptions that tended to occur for parameters that were near the analytical detection limit, or for some additional parameters as described below. Similarly, charge balances, method blanks and method spikes for aqueous analyses returned QA / QC data that was within expected benchmarks with rare exceptions that were also associated with low concentrations near the analytical detection limit.

Results obtained from SGS Lakefield and Global ARD were also compared to each other as part of QA / QC checks. In general, results of ABA and elemental content analyses were determined to be reasonably consistent. However, key differences in SFE leachate quality were noted between the datasets from each laboratory, as described below. Re-analysis was completed at SGS Lakefield, Global ARD and a third laboratory (BV) to resolve the differences.

Results of re-analyses completed are described below.

[15] SFE testing initially completed on 155 samples, however, results for 29 samples were deemed to be invalid through a QA / QC program. See Section 7.2.4.
[16] Some variability in SFE results was noted for the subsamples collected from the locations selected for field testing, and results of triplicate analyses were therefore evaluated individually.

ABA Testing

- Three samples had slightly negative Modified NP values. Results were validated through re-analysis of two samples, which showed similar Modified NP results with the absolute difference ranging from 0.3 to 1.5 $CaCO_3$/t. This was considered to be acceptably repeatable. As discussed in Section 7.3.5, some samples have a very low neutralization capacity and some variability between subsamples commonly occurs when analyzing geologic materials.
- An additional 22 samples with low CarbNP based on TIC content below the analytical detection limit (<0.02% TIC) were reanalyzed. Results of the reanalysis remained consistently below the analytical detection limit for all 22 samples reanalyzed.

SFE Testing

SFE testing was completed on 155 samples, with 29 samples tested at SGS Lakefield and 126 samples tested at Global ARD. As previously noted, key differences were noted between the datasets from each laboratory:

- Leachates from SGS Lakefield had concentrations of iron and some trace metals that were elevated relative to screening values. This was initially attributed to the presence of colloids and / or the physical disturbance or dissolution of iron oxyhydroxide minerals (which are often associated with trace metals). The leachate pH from samples tested at SGS Lakefield was on the order of pH 8 to 9.
- While SFE leachates from Global ARD had similar major ion composition to leachates from SGS Lakefield, they had a lower pH (on the order of pH 6.5) and notably lower iron and metal concentrations overall. Very few of the leachates from Global ARD had metals greater than screening values.

Routine QA / QC checks (review of charge balance, method blanks and laboratory duplicates) of data received from each laboratory did not identify any apparent issues with the analyses. The samples also comprised analyses conducted over multiple batches and dates at each laboratory. ABA and solid phase metal content results were consistent among the samples and could not explain the systematic differences observed between SFE test results from SGS Lakefield versus Global ARD.

Therefore, to further evaluate the apparent differences between the two laboratories, additional analyses were conducted:

- 10 samples originally analyzed at Global ARD were analyzed at SGS Lakefield.
- 15 samples originally analyzed at SGS Lakefield were analyzed at Global ARD.
- Global ARD re-analyzed an additional 15 samples from their sample set to confirm their results were repeatable.

Verification testing was conducted at BV. This included full SFE testing of 21 samples, 10 of which have previously undergone SFE testing at both SGS Lakefield and Global ARD, and 11 which have been previously tested at Global ARD. Preserved leachates including 10 SFE leachates from SGS Lakefield and 14 SFE leachates from Global ARD were also reanalyzed at BV to rule out any issues with the ICP analysis. Results are shown in Appendix M2 for all three laboratories.

- The Global ARD results were confirmed to be repeatable.
- Re-analysis of the samples confirmed consistent differences between Global ARD and SGS Lakefield in terms of the pH and metal content of the SFE leachates as presented in Table M-6.
- Results from the third laboratory (BV) were generally consistent with the Global ARD results. This confirmed the systematic differences noted between SFE leachates from SGS and leachates from other laboratories.

The SFE test results from the initial 29 samples conducted at SGS Lakefield are considered invalid based on the above QA / QC assessment and are not used as part of the baseline program for comparison with screening values. Subsequent discussions with SGS Lakefield could not clearly confirm detailed method information. It was unclear if the samples had undergone end over end shaking or if sufficient settling of particles was allowed after shaking and prior to leachate filtration. The observed differences in the data were attributed to differences in methods used.

7.2.5 RESULTS

Static test results for overburden samples are tabulated in Appendix M1 and presented in the following sections.

Acid Generation Potential

- The total S content of the overburden samples was very low overall, with approximately 30% of the samples below detection (<0.005% or <0.01%[17]). When detectable, total S concentrations ranged from 0.006% to 0.11% (median of 0.010%; Table M-2). Samples located proximal to the bedrock-overburden interface (i.e., within 5 m of the interface) had a similarly very low total S content.
- The sulphate S content of the samples was also very low and 115 samples (67%) had a sulphate S content below the analytical detection limit [18].
- The relationship between sulphide S and total S is presented in Figure 7.2-2. For samples with sulphate S content below detection, sulphide S was assumed to be equal to total S to be conservative.
  - For most samples tested, S was predominately present as sulphide S.
  - For a small proportion of the samples (approximately 26%) sulphate represented at least half of the total S present, including 24 samples in which sulphate comprised all the S present. This was attributed to the low total S content of the samples (equal to or slightly greater than the detection limit for sulphate S) and sulphate S being measured at or near the detection limit for these samples. Sulphate minerals were not detected by mineralogical testing.
- A comparison of TC versus TIC is presented in Figure 7.2-3 and indicates that C was predominately present as inorganic C in most samples tested, presumably as carbonate minerals. A small proportion of the samples (approximately 22%), had TC contents that were several times greater than their TIC content, suggesting the presence of organic C in these samples. A subset of these samples (n=22) underwent re-analysis which confirmed the TC and TIC results for the samples.
- Modified NP values were variable and ranged from approximately -0.7 to 135 kg $CaCO_3$/t (median 7.7 kg $CaCO_3$/t; Table M-2).
  - Samples with higher neutralization capacity generally comprised glaciolacustrine sediments (upper- and lower-unit material types), while samples with low levels of neutralization capacity often comprised sandy glaciolacustrine (shoreline) and glaciofluvial materials. Materials with lower neutralization capacity typically contained more quartz and plagioclase by R-XRD than samples with higher neutralization capacity, which had detectable levels of carbonate minerals. Samples with lower Modified NP values were located throughout various Project locations and included samples collected at surface as well as proximal to the bedrock-overburden interface (within 5.0 m).
  - Results indicated that three samples had slightly negative Modified NP (-0.4 to -0.7 kg $CaCO_3$/t). Two of the samples were re-analyzed along with a subset of other low NP samples (n=5, <2 kg $CaCO_3$/t) and results showed minor variation around the original NP results, with the absolute difference in results ranging from 0.3 to 1.5 kg $CaCO_3$/t. The negative NP content for these samples was attributed to analytical variability rather than stored acidity, based on the overall ABA results of the samples.

[17] The detection limit for total S was 0.005% for samples WSP 01 through WSP 30 and 0.01% for samples WSP 31 through WSP 116.
[18] The detection limit for sulphate S was 0.04% for samples WSP 01 through WSP 30 and 0.01% for samples WSP 31 through WSP 116.

- The paste pH of the samples was generally circumneutral to mildly alkaline, with a median paste pH of 8.3. Twenty-nine samples (approximately 16% of the samples analyzed) had lower paste pH values, ranging from 4.6 to 6.4. The maximum paste pH among the samples was 9.8 (Table M-2).
  - Samples with paste pH<6.5 had total S content ranging from below the detection limit up to 0.04% (median of 0.01%) and contained non-detectable to low levels of NP (Figure 7.2-4). The observed paste pH for these samples was attributed to the pH of the deionized water used in the test (pH 5 to 6), as these samples contained effectively no acid generating or neutralizing content. Many of these samples also comprised glacial sands and the lower paste pH results may also be influenced by the abrasion pH of quartz (pH 6).
- A comparison of Modified NP and CarbNP is presented in Figure 7.2-5. Results indicate that CarbNP values were similar to Modified NP values for most samples with NP content greater than 20 kg $CaCO_3$/t, suggesting that neutralization capacity was predominantly present as carbonate minerals in these samples. For samples with NP content of less than 20 kg $CaCO_3$/t, CarbNP values were typically lower than Modified NP values, suggesting that non-carbonate minerals may provide some of the neutralization capacity in these samples. Many samples with a Modified NP less than 10 kg $CaCO_3$/t had non-detectable CarbNP and no detectable carbonates by R-XRD. One sample (WSP 04) had notably lower CarbNP content (4 kg $CaCO_3$/t) than Modified NP content (on the order of 51 kg $CaCO_3$/t) suggesting that non-carbonate minerals may comprise a large portion of the neutralization capacity in this sample. This sample appears to be an outlier, as other samples had good agreement between Modified NP and CarbNP.

As previously described, acid generation potential was evaluated based on the sample's NPR, which was calculated by two approaches, including CarbNPR (CarbNP/MPA) and NPR (NP/AP). Some samples had a sulphide S content (calculated by difference) of zero. In those cases, acid generation capacity was represented by MPA (based on total S).

Consideration of CarbNPR and NPR gave consistent results with approximately 96% of the samples (n=165) classified as NPAG (Figure 7.2-6 and Figure 7.2-7). The average CarbNPR for overburden samples was 37 and the average NPR was 60.

Eleven samples had CarbNPR ≤2 and / or NPR ≤2. Of these samples, only three had CarbNPR and NPR ≤2. These samples generally consisted of glacial sands with no neutralization capacity and total S contents that were at, or very close to, the analytical detection limit. These materials are not considered a risk for acid generation.

Acid generation potential was also evaluated by NAG pH testing (single addition). Testing was completed on a subset of 100 samples. Results for the single-addition NAG testing are presented in Table M-2 and summarized below.

- All 100 samples tested by the NAG test (including the samples with negative and low NP) had a NAG pH >4.5 suggesting that all samples were NPAG.
- Most of these samples (n=90) were also classified as NPAG by ABA testing (i.e., CarbNPR / NPR >2).
- The remaining 10 samples for which NAG pH data is available had low total S content (ranging from <0.01% to 0.08%) and a low CarbNP and Modified NP content but had an NPR or CarbNPR ≤2. All of these samples were indicated to be NPAG by the NAG pH test (Figure 7.2-8 and Figure 7.2-9).

Elemental Content

Results of elemental content testing were compared against the qualitative screening values discussed in Section 7.2.3. Comparisons against screening values are for assessment purposes only and hold no regulatory significance.

Solid phase concentrations of metals of key relevance to ML / ARD were low and several were below analytical detection limits (Table M-3).

- One sample had As content marginally higher than the 10 times crustal abundance screening value (18 mg/kg).

- One sample had Ag and W concentrations greater than the 10 times crustal abundance screening values (0.75 mg/kg and 13 mg/kg respectively).
- Hg concentrations were below the screening value (0.85 mg/kg) for all samples and below the analytical detection limit (<0.05 mg/kg or <0.005 mg/kg [19]) for approximately 60% of samples (n=102).

The following observations were made with respect to the Ontario Typical Range soil screening standards:

- All samples had elemental concentrations that were below screening values for B, Be, Cd, Co, Hg, Ni, Pb, Sb, Se, Tl and Zn.
- Isolated samples were slightly greater than the screening values for As (n=1; 18 mg/kg), Ba (n=1; 220 mg/kg), Cu (n=1; 92 mg/kg), Mo (n=4; 2 mg/kg), U (n=2; 2.5 mg/kg) and V (n=6; 86 mg/kg).
- Cr concentrations were marginally greater than Ontario Typical Range screening values for 57% of the samples (n=98).
- Analytical detection limits were higher than the screening value for Sb in some samples (n=30; 1.3 mg/kg) and Ag (n=24; 0.5 mg/kg). As a result, some samples appeared to have concentrations greater than the screening values for those parameters; however, concentrations were below the detection limits. Samples analyzed with lower detection limits (n=142) had Ag and Sb concentrations below screening values.
- Mercury concentrations were below the screening value for all samples and below the analytical detection limit for approximately 60% of samples (n=102).

Metal Leaching Assessment

SFE test results were available for 126 samples. SFE results were compared against PWQO values for screening purposes, including both the in-place and interim PWQO values (Table M-4). Comparisons against screening values are for assessment purposes only and are used to identify parameters of potential interest for a project but hold no regulatory significance and are not a direct indicator of drainage quality. The metal leaching potential of the overburden is being confirmed as part of ongoing kinetic testing programs, as summarized in Section 7.3.

Table 7.2-4 summarizes comparison of the SFE test results to the screening values. Concentrations of many parameters were below screening values in most samples. The following observations are provided with respect to qualitative screening criteria:

- Aluminum concentrations were higher than the PWQO screening values in approximately half (n=76) of the samples tested; however, this was attributed to the presence of colloidal Al as a result of the testing procedure and is unlikely to be observed under field conditions. Sixteen samples had Fe concentrations in leachates slightly greater than the in-place PWQO value (0.3 mg/L). A strong relationship between SFE leachable Al and Fe was observed. It is inferred that the observed Fe concentrations are due to the presence of colloidal Fe from the physical disturbance of iron oxyhydroxide minerals present in the samples, or the dissolution of iron oxyhydroxide minerals in the deionized water used in the test (which is mildly acidic). Such concentrations are unlikely to be observed under oxic field conditions at neutral pH.
- Concentrations of Ag, Cr and Cu were greater than PWQO screening values (0.0001 mg/L, 0.001 mg/L and 0.005 mg/L respectively) in approximately 15% of samples. Concentrations were only slightly greater than the screening values and samples were not noted to be enriched in solid phase metals relative to 10 times crustal abundance screening values.

[19] The detection limit for Hg was <0.05 mg/kg for the samples analyzed at SGS Lakefield (WSP 01 through WSP 30); for the samples analyzed at Global ARD the detection limit for mercury was <0.005 mg/kg.

- Concentrations of some parameters, including As, Co, W, U, V and Zr, were slightly greater than their respective screening values in isolated samples as indicated in Table 7.2-4. These were isolated samples and do not represent concentrations expected in site drainage.
- Mercury concentrations were below the screening value for all samples and below the analytical detection limit for 96% of samples (n=121).

Bulk Mineralogy

Mineralogical testing was completed on 31 overburden samples to determine their mineralogical composition including the presence of acid generating and acid neutralizing minerals. Results are provided in Table M-5. Key observations from testing are summarized below:

- No sulphide minerals were identified in any of the samples analyzed. This aligns with the very low total S content of the samples.
- Carbonate minerals were present in 43% (n=13) of the samples as calcite (0.45 to 5.4 wt.%) and dolomite – ankerite (0.68 to 5.8 wt.%). These samples also reported the highest TIC results in ABA analysis and TIC calculated from R-XRD results was consistent with the ABA results. The remaining 18 samples analyzed contained no detectable carbonate minerals. Results of ABA analyses indicated that most of these samples had low but detectable Modified NP (ranging from -0.7 to 8.5 kg $CaCO_3$/t) suggesting that some of the aluminosilicate phases identified below (e.g., plagioclase feldspar, illite-smectite, clinochlore, vermiculite) may contribute a small amount of neutralization capacity to overburden materials.
- Feldspars were identified in all samples, including unspecified plagioclase feldspar (18 to 43 wt.%) and unspecified potassium feldspar (10 to 14 wt.%).
- Oxide minerals identified in the samples include quartz, which was present in all samples with concentrations ranging from 14 to 44 wt.%, and magnetite, which was present in small amounts (<0.8 wt.%) in 19 of the samples.
- Phyllosilicates were identified in all samples including illite-muscovite (1.2 to 9.7 wt.%), illite-smectite (2.7 to 7.5 wt.%), biotite (0.7% to 5.3 wt.%), clinochlore (0.5 to 6.1 wt.%), kaolinite (0.98 to 3.9 wt.%), montmorillonite (0.23 to 26 wt.%.) and vermiculite (0.24 to 1.5 wt.%). Most samples contained illite-muscovite, biotite and clinochlore. Approximately half of the samples analyzed contained illite-smectite and montmorillonite. Kaolinite and vermiculite were present in some of the samples analyzed.
- Other silicate minerals identified included amphibole (1.9 to 5.3 wt.%) in 25 samples, clinozoisite (0.7 to 2.8 wt.%) in 23 of the samples and actinolite (2.1 to 5.1 wt.%) in six samples. Minor amounts of titanite (0.32 to 0.61 wt.%) were also identified in 10 samples.
- Trace amounts of the phosphate mineral apatite (0.17 to 0.25 wt.%) were identified in three of the samples.

7.2.6 KEY FINDINGS

- Geochemical testing indicates that the overburden is NPAG based on an average CarbNPR of 37. The samples had a very low total S content; total S was below the analytical detection limit in approximately 30% of the samples. Where detectable, total S concentrations ranged from 0.006% to 0.11%.
- Ninety-six percent (96%) of the samples (i.e., n=165 samples) had a CarbNPR >2 and were considered NPAG. Seven samples had a CarbNPR ≤2 and generally consisted of glacial sands with no neutralization capacity and S contents that were at or very close to the detection limit. These materials are not considered a risk for acid generation. This was consistent with NAG test results that indicated that these samples were NPAG.
- The samples had a low solid phase metal content that was generally below screening values. Solid phase Hg concentrations were below screening values for all samples and below the analytical detection limit for approximately 60% of samples (n=102).

- Metals concentrations in SFE leachates were generally below qualitative screening criteria for most parameters. Hg concentrations in SFE leachates were below analytical detection limits for 96% (n=121) of the samples and below screening values for all samples. Results from the SFE tests do not represent drainage quality, but act as screening tool to identify parameters of potential interest. Kinetic testing is ongoing to assess metal leaching potential from Project overburden.
- Mineralogical testing indicated that no S-bearing phases (sulphide minerals or sulphate minerals) were detected in the overburden samples. Some samples contained carbonate minerals including calcite, along with aluminosilicate phases and quartz. These results were consistent with the ABA test results for the samples.

Table 7.2-1: Overburden Sample Summary by Location

Location	Number of Samples
AEX Program Site (within mine main site area)	28
Open Pit (LP Central pit and Viggo pit)	40
Stockpile Area	27
Process Plant Site	12
Collection Water Pond	4
Main Collection Channel	6
Effluent / Fresh Water Pipeline	1
Sand and Gravel Pit 3	7
Sand and Gravel Pit 3B	16
Sand and Gravel Pit 4	3
Sand and Gravel Pit 5	1
Sand and Gravel Pit 6	5
Tailings Management Facility	7
Other (1)	15
Total	**172**

Note:
1 Samples collected from areas outside of the proposed Project development footprint (potential process plant site).

Table 7.2-2: Overburden Units

Overburden Unit	Number of Samples	Description
Glaciolacustrine Shoreline	18	Sand and silt, includes gravel and cobbles at some locations; shoreline and shallow water deposits.
Glaciolacustrine Upper Sediments	44	Clay, deep water deposits, often varved with silt laminae; includes clayey silt.
Glaciolacustrine Lower Sediments	14	Silt, shallow water deposits from early glacial lake, occurs below the clay rich glaciolacustrine deposits; includes sandy silt, sand beds and / or clay laminae.
Glaciofluvial Sediments	54	Sand and silty sand, can include gravel, outwash deposits that may have formed in subaqueous fans and similar environments.
Glacial Till	36	Mixture of sand, silt, gravel, cobbles, boulders, and some clay; likely deposited subglacially; may include some stratified deposits; also referred to as moraine; often interspersed with bedrock outcrops.
Mixed	**6**	Overburden materials from the large scale field test samples. Overburden was mixed by excavator to homogenize for field testing.
Total	**172**	

Table 7.2-3: Analytical Program Summary

Analysis	Number of Samples (1)
ABA	172
NAG pH	100
Elemental Content	172
SFE	126
R-XRD	31

Note:
1 Does not include additional QA / QC testing on the samples (see Section 7.2.4).

Notes:

Sulphide S determined by difference (total S - sulphate S). Where sulphate S was below the detection limit, sulphide S was assumed to be equal to total sulphur.

WSP 01 through WSP 30 were analyzed at SGS with a detection limit of 0.005% for total S and 0.04% for sulphate S. The remaining samples were analyzed at Global ARD with a detection limit of 0.01% for both total S and sulphate S.

Soil types were inferred based on test pit and borehole logs; samples marked with an X were collected within 5 m of the bedrock interface.

7.3 KINETIC TESTING

7.3.1 PROGRAM OVERVIEW

A kinetic testing program for the Project was initiated to supplement the static program and further evaluate the potential drainage quality from overburden materials that will be relocated as part of site development. Additional kinetic tests, consisting of large-scale field leach tests, are under construction.

The samples selected for kinetic testing included a range of materials representing the overall overburden characteristics based on the static testing database (n=172 samples). Although the overburden has a very low sulphur content and low metal content, samples with more conservative (i.e., relatively higher S, lower neutralization capacity, and higher metal contents) were also included. Kinetic test results are available for 14 tests as follows:

- 47 weeks of data (n=1 test).
- 37 weeks of data (n=2 tests).
- 26 weeks of data (n=1 test).
- 12 weeks of data (n=9 tests).
- 8 weeks of data (n=1 test).

There are no regulatory criteria to assess metal release data from kinetic tests for overburden. The approach and testing methods utilized herein are based on the requirements of the Ontario *Mining Act*; namely guidance found within the reference document *Prediction for Drainage Chemistry for Sulphidic Geologic Materials* (MEND 2009), which represents best practice and industry-standard approaches and methodologies for ML / ARD sampling and characterization in Canada.

It is noted that static testing (Section 7.2) demonstrated that the overburden samples were NPAG with very low S contents (typically below analytical detection limits) and low solid phase metal contents. Typically, materials with very low sulphide and metal contents below screening values are considered a low risk for ML / ARD and are not subject to kinetic testing; kinetic tests usually focus on material with a higher S or metal content considered to pose a potential risk. Despite this, the Project utilized a proactive and protective approach and included kinetic testing on overburden for completeness.

7.3.2 TRICKLE LEACH COLUMN TESTING PROGRAM

The current kinetic testing program consists of 14 trickle leach columns and three method blank columns as summarized in Table 7.3-1. These tests were initiated in 2024 and 2025 at Global ARD in Burnaby, and 8 to 47 weeks of test results are available.

Kinetic testing was initiated on overburden samples following the completion of static testing (kinetic test results presented in Appendix N). Samples selected for kinetic testing include 11 samples considered to be representative of the range of geochemical characteristics of Project overburden, and three samples of outlier materials (e.g., relatively lower NP and higher S contents) collected from the near surface. These samples are described below:

- Four samples with low total S content (i.e., at or below the analytical detection limit of 0.01%), which is common for Project overburden. Low S samples included in the kinetic testing program included three samples with low to typical solid phase metals content and very low neutralization capacity (COL-2, COL-7 and COL-9), and one sample (COL-6) with higher neutralization capacity (approximately 80th percentile) and a higher metals content relative to other overburden samples.
- Two samples with total S contents considered typical based on the average total S observed in the overburden database (i.e., 0.02%). This included one sample (COL-12) that had average to low neutralization capacity (i.e., 2nd percentile CarbNP and 54th percentile Modified NP) and a higher

metals content relative to other samples, and one sample (COL-4) with higher neutralization capacity (i.e., approximately 80th percentile CarbNP and Modified NP content) and typical metals content [20].

- Five samples with total S content considered elevated relative to the overall database (i.e., 0.03 to 0.06%, representing 81st to 94th percentile S content of overburden), although the S content of these samples was still considered to be very low. These samples were selected to represent the range of neutralization capacity and metals content as described below:
  - Three samples with low to typical neutralization capacity compared to other samples (i.e., approximately 2nd to 60th percentile CarbNP and 40th to 60th percentile Modified NP content). Two of these samples had generally typical solid phase metal content (COL-14 and COL-16) and one sample (COL-8) had a higher metals content relative to other overburden samples.
  - Two samples (COL-1 and COL-10) with higher neutralization capacity (i.e., approximately 90th percentile CarbNP and Modified NP content) and a higher solid phase metals content relative to other overburden samples.

Three outlier samples with low NP, low CarbNP and a range of S and metals contents were also tested for completeness. These three samples had NPR ≤2 but were NPAG based on NAG testing and are not considered a risk for ARD. All three of these samples had CarbNP that was based on TIC below the analytical detection limit and were collected from shallow depths within 10 cm of overlying organic material. Additionally:

- COL-3 was prepared with a glaciofluvial sample that had a very low Modified NP content (0.4 kg $CaCO_3$/t; 2nd percentile). The sample had a total S content that was higher relative to other samples (0.03%; 81st percentile) and typical metals content in comparison to the overburden database.
- The COL-13 sample had a negative NP (-0.7 kg $CaCO_3$/t), S that was below the analytical detection limit, and low metals content. Despite the low S content (<0.01%), the sample had an NPR ≤2 due to the lack of NP in the sample.
- The COL-15 sample had higher metals and a higher S content in comparison to the overburden database (0.05%; 92nd percentile) and a low NP.

At the initiation of testing, all columns were flushed weekly with 0.35 L deionized water. The weekly flushing volume was reduced to 0.18 L to represent a reasonable approximation of the expected rainfall infiltration to overburden ratio under field conditions. These reductions occurred in week 15 for COL-1, in week 18 for COL-2 through COL-4, and in week 24 for COL-5 (method blank). The remaining column tests (COL-6 through COL-17) were initiated at a later date and the flushing volume has not yet been reduced. The flushing volume for these tests will be reduced after 18 weeks of testing for consistency with the other tests.

During the testing period, two of the samples containing fine grained material (COL-1 and COL-3) consolidated (after 47 and 26 weeks) such that sufficient leachate could not pass through the sample for analysis. These samples were removed from the columns, air dried and gently rolled to break up the material in an attempt to encourage better drainage. After replacing these samples in the columns, the issues with drainage remained and these two columns were therefore terminated after 47 weeks of testing (COL-1) and 26 weeks of testing (COL-3). ABA testing and elemental content analyses were completed on the column residue at termination. Results of termination testing are provided in Appendix N1 (Table N-4 through N-6).

Results of trickle leach column tests were compared to the range of concentrations observed from several key site surface water monitoring stations for screening purposes only. Surface water monitoring stations were selected based on proximity to future site infrastructure. Data from 2020 to 2024 was used for comparisons. Secondary screening was also completed using in place and interim PWQO values to

[20] Statistical descriptions are relative to the overburden ML / ARD database. Low refers to concentrations that are lower than the 40th percentile rank, Typical refers to samples with concentrations between the 40th and 75th percentile rank, and Elevated is greater than the 75th percentile rank.

support a qualitative assessment of column test results. Comparison to PWQO is for screening purposes only and has no regulatory significance.

7.3.3 QUALITY ASSURANCE AND QUALITY CONTROL

Kinetic test data was validated through review of charge balance information, blank column data and assessment of analytical spikes in the data, if present.

Method blank column data usually showed dissolved metals concentrations that were below or near the analytical detection limit, as expected. No QA / QC issues were noted in kinetic test data.

7.3.4 RESULTS

Results of the overburden kinetic tests are summarized below and presented in Appendix N. This includes data collected up to July 2025 (e.g., 8 to 47 weeks of testing as indicated in Table 7.3-1).

Results are presented as the concentrations measured in column leachate and are compared to water quality screening values, including surface water quality data from key stations monitored between 2020 and 2024 as part of baseline studies for the Project. Comparisons were also made to PWQO values. These comparisons were completed to identify potential parameters of interest in drainage from overburden materials. Steady-state conditions for the drainage quality were based on the median concentration over the last five weeks of monitoring.

As presented in the previous section, overburden at the Project has very low total S content (average 0.02%), no detectable sulphide minerals, and low to moderate CarbNP (average 21 kg $CaCO_3$/t). As described in Section 7.3.2, samples included in column testing include those representing the range of characteristics for overburden based on static testing results, including 11 samples representative of the bulk of the overburden at the project, and three samples that were considered to be outlier materials (COL-3, COL-13 and COL-15).

Key observations from the tests containing material representative of expected overburden quality (COL-1, COL-2, and COL-4 through COL-12, COL-14 and COL-16) are summarized below and presented in Appendix N2:

- Leachate pH generally ranged between 6.2 and 8 (Figure N2-1).
- Sulphate concentrations in column leachate were low, generally below 10 mg/L (Figure N2-5) following the first five weeks of testing. This was observed for all tests, including columns containing samples with a higher solid phase S content relative to other samples (i.e., 0.03 to 0.06%). Sulphide mineral contents in the samples were also low, and as such these samples are not expected to be a notable source of sulphate release due to sulphide oxidation.
- Alkalinity concentrations were noted to be higher (ranging from approximately 50 to 150 mg/L $CaCO_3$/L; Figure N2-4) in leachate from columns containing samples with detectable CarbNP (i.e., COL-1, COL-4, COL-6, COL-8, COL-10, COL-14 and COL-16). Alkalinity concentrations were notably lower (i.e., 5 to 20 mg/L $CaCO_3$/L) in the leachate of columns that contained samples with CarbNP based on TIC below the detection limit (COL-2, COL-7, COL-9 and COL-12), as expected.

Metal concentrations in test leachates were low and showed stable to decreasing trends throughout testing for most parameters. Mercury was consistently below the CVAA detection limit (0.000005 mg/L) in all test leachates, and results of ultra-trace mercury analyses indicated concentrations were up to two orders of magnitude lower than the CVAA detection limit.

One test containing a sample with overall low solid phase metals concentrations that were higher relative to other overburden samples (COL-12) showed an increasing trend in leachate concentrations for a few parameters, including Be, Cr, Ni, Pb, Tl, Zn, and Zr, although concentrations of these parameters remained low. Similar trends were not noted in other columns containing samples with similar metals content. (COL-1, COL-6, COL-8, COL-10 and COL-15).

Metal concentrations in test leachates did not appear to be affected by the change in flushing rates for COL-1 through COL-5 (Figures N2-1 to N2-36 in Appendix N2).

For context, median metals concentrations in column leachates from the last five weeks of available data were compared to surface water quality data from several baseline water quality monitoring stations across the future Project footprint, as summarized in Table 7.3-2 and shown in Figures N3-1 through N3-25 (Appendix N3). Median concentrations were calculated from concentrations observed at the reduced flushing volume (0.18 L) for COL-1 through COL-5 and from concentrations at the original flushing volume (0.35 L) for COL-6 through COL-17.

Most parameters had median concentrations in column leachates that were comparable to or lower than those observed in surface waters at site. One test (COL-14) had W concentrations in leachate that were slightly above the range observed in site surface waters however, those concentrations were well below PWQO values. This was attributed to the sample's solid phase W content, which, while below screening values, is considered high (94th percentile) relative to the rest of Project overburden. Concentrations of many parameters (including CVAA Hg) were consistently below analytical detection limits in all column tests.

Median concentrations over the last five weeks of testing were also compared to in-place and interim PWQO values. However, laboratory test concentrations are not a direct indicator of drainage quality and this comparison implies neither compliance nor non-compliance with water quality objectives. Key observations from the screening conducted on column leachates are summarized below for key parameters of interest and presented in Table 7.3-2.

- Columns considered representative of Project overburden had leachate concentrations that were below PWQO screening values in all leachate samples for most parameters, including Hg.
- The median leachate concentrations through the last five weeks of testing were generally below PWQO screening values for all parameters, with many parameters (including CVAA Hg) below analytical detection limits.
- Median concentrations of Al in COL-9, COL-12, COL-14 and COL-16 were slightly above the interim PWQO screening value (0.075 mg/L), which was attributed to the dissolution of aluminosilicate minerals caused by flushing by deionized water during the laboratory test.
- Isolated parameters had median concentrations through the last five weeks of testing that were greater than PWQO screening values in some of the test leachates. This included two tests (COL-4 and COL-12) with Cr slightly greater than the PWQO screening value (0.001 mg/L), three tests (COL-4, COL-6 and COL-14) with U slightly greater than the interim PWQO screening value (0.005 mg/L), and one test (COL-12) with Fe slightly greater than the PWQO screening value (0.3 mg/L). In all cases, these elements were within the range of measured site surface water quality concentrations.

Key observations for the three outlier samples (i.e., lower NP and relatively higher sulphur content; COL-3, COL-13 and COL-15) are summarized below. As previously noted, the samples had an NPR or CarbNPR ≤2 but NAG testing indicated the samples were NPAG. These samples are not expected to represent the bulk of the overburden at the Project based on the sample's low NP and / or CarbNP relative to the majority of overburden at the Project, as well as the shallow collection depth and proximity to organic material. Of note, overburden at the Project ranges up to 20 m in thickness and averages 10 m and organic material is typically limited and represents a small proportion of surficial materials.

- The pH of leachate from two of the three columns (COL-13 and COL-15) was generally between 6 and 6.5.
- Alkalinity in these two columns was approximately 10 mg $CaCO_3$/L despite low CarbNP (based on below detection limit TIC concentrations) and low NP content of these samples.
- Leachate sulphate concentrations were low and decreased throughout the test to values less than 5 mg/L (COL-15) or below detection (COL-13, 0.2 mg/L) which is indicative of considerably low to no sulphide oxidation in the tests.

Steady-state leachate metals concentrations in COL-13 and COL-15 were comparable to, or lower than concentrations observed in surface waters at site (Figures N3-1 to N3-35 in Appendix N3). Steady state

leachate concentrations were compared to PWQO values for reference purposes only. As described above, laboratory test concentrations are not a direct indicator of drainage quality and this comparison implies neither compliance nor non-compliance with water quality objectives. Steady state leachate concentrations were below screening values in COL-13 and were below screening values for most parameters in COL-15 except for Cr and Fe (Table 7.3-2). These elements were within the range of measured site surface water quality concentrations.

In comparison, leachate pH from the third outlier sample (COL-3) was slightly lower (approximately 4.5 to 6) and highly consistent with the method blank columns (COL-5, COL-11 and COL-17). This was attributed to the pH of deionized water used in the laboratory test, as well as the low NP of the sample and the influence of natural organic acids that may have been present as the sample was collected near the soil interface. Sample logs indicated that bulk organic matter was present above the sample interval and TC levels in the sample aligned with the potential presence of organic C. The sample had a very low sulphur content overall (0.03%) and leachate sulphate concentrations were low, indicating that sulphide oxidation was not driving the pH response of this test.

Leachate from COL-3 was generally noted to have slightly higher concentrations of metals than leachate from the other column tests, however, concentrations remained low and generally within the range of surface water concentrations at the Project. Steady state leachate metals concentrations were usually below PWQO screening values for most parameters except for Al, Cr, Co, and Fe, which were attributed to the leachate pH in the test, and which was previously noted to be influenced by deionized water used in laboratory testing and the presence of natural organic acids.

Drainage quality similar to COL-3 is not anticipated to occur under field conditions, as testing indicates that most overburden materials produce alkalinity which provides buffering capacity to the drainage.

Twelve of the laboratory-based trickle leach columns containing overburden samples remain in operation and will continue to be monitored to assess the metal leaching potential of the overburden. Field kinetic testing of overburden samples as described in Section 7.3.6 is also planned for 2025 to assess potential drainage quality under field conditions.

7.3.5 KEY FINDINGS

Leachate from columns containing samples that are representative of the bulk of the overburden at the Project (COL-1, COL-2, COL-4, COL-6, COL-7, COL-8, COL-9, COL-10, COL-12, COL-14 and COL-16) remained stable at pH values of approximately 6 to 8 throughout the entire testing period. Metal concentrations were similar to surface water quality concentrations from the Project site and were generally below PWQO screening values. Isolated parameters had concentrations in leachate greater than site surface waters (W) or PWQO screening values (Al, Cr, Fe and U) in one to five of the tests. Many parameters, including Hg, were below PWQO screening values in all data collected from the column tests. Results of kinetic testing are not indicative of a concern for metal leaching from overburden.

Three outlier samples were included in the column testing program. These samples had low NP and a range of S contents (<0.01 to 0.05%). Owing to their low NP content they had an NPR ≤2 but NAG testing indicated they were NPAG. Leachate pH was generally between 6 and 6.5 for two of the three samples, consistent with some of the more representative overburden samples. Both samples had leachate concentrations of metals that were within the range of surface water concentrations at the Project, and the majority of parameters were also below PWQO and / or interim PWQO values for both columns.

Leachate pH for one of the outlier samples (COL-3) was notably consistent with the blank columns. This was attributed to the pH of deionized water used in the laboratory test, as well as the low NP of the sample and the potential influence of natural organic acids that may have been present in the sample. The sample had a very low sulphur content overall (0.03%) and leachate sulphate concentrations were low, indicating that sulphide oxidation was likely not driving the pH response of this test. Similar drainage quality is not anticipated to occur under field conditions, as testing indicates that in contrast to the COL-3 sample, most overburden materials produce alkalinity which provides buffering capacity to the drainage.

Trickle leach column testing is ongoing for 12 of the samples, and construction of field kinetic tests for overburden materials is underway. These tests will be used to further assess overburden metal leaching potential under field conditions.

7.3.6 FIELD CELL TESTING

Construction of field tests is underway at the site to further assess overburden drainage quality under field conditions. Large quantity overburden samples (3 to 4 m^3) were collected from six locations throughout the Project where relocation of overburden for mine development will be required. Material from each sampling location selected for field testing was homogenized in the field and three representative subsamples (replicates) were collected from each location and submitted to the laboratory for static analyses. Results from laboratory static testing completed on the samples were reported in Section 7.2.5.

The current proposed configuration of field tests consists of open-top HDPE 4,000 L totes equipped with a basal drain. The tote will be mounted on a platform at a slight angle to facilitate drainage through the basal drain. A quartz sand filtration bed and geotextile liner will be added to the bottom of the tote, which will be connected to a sealed leachate collection pail with clear vinyl tubing and PVC fittings. The homogenized test material will be placed in the bottom of the lined tote. The field test will be open to precipitation and drainage from the overburden will be directed via vinyl tubing to the collection pail.

Leachate samples will be collected at regular intervals from the collection pail according to the frequency and procedures described in Section 4.5 and in tandem with sampling events for the FLB tests. Test leachate will be monitored for the parameters listed below. The order of parameters listed was established as the priority for sample collection, in the event of low volumes in leachate pails, that may occur during periods of low precipitation:

- Field parameters (temperature, pH, conductivity).
- Dissolved Hg.
- Dissolved metals (Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Mg, Mn, Mo, Na, Ni, P, Pb, Sb, Se, Sr, Ti, Tl, U, V, W, Zn and Zr).
- General chemistry: anions by IC (sulphate, Cl, F), alkalinity, lab pH and conductivity.
- Total P.
- Acidity.
- TDS.

Results will be reviewed as available and reported as appropriate.

Notes:

1 Screening was conducted on the median concentration in leachate over the last five weeks of testing, which represents metal release at decreased flushing rates for COL-1 and two weeks of data with decreased flushing rates for COL-2 through COL-4. Screening was conducted for assessment purposes only and holds no regulatory significance.

2 Bolded values indicate metal concentration greater than interim PWQO screening value.

3 Shaded cells indicate metal concentrations greater than in-place PWQO screening value.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

Table B-1. Acid Base Accounting Results

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

Table B-1. Acid Base Accounting Results

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

Table B-1. Acid Base Accounting Results

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

Table B-1. Acid Base Accounting Results

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

Table B-1. Acid Base Accounting Results

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).

(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S or 31.25*ICP-S (aqua regia) if Total S by Leco was unavialable (see text).

(3) Neutralization Potential measured by Modified Sobeck Method.

(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.

(5) Carbonate Neutralization Potential calculated from TIC.

(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.

Classification as mine rock or ore-grade materials was based on gold content.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).
(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S.
(3) Neutralization Potential measured by Modified Sobeck Method.
(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.
(5) Carbonate Neutralization Potential calculated from TIC.
(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.
Classification as mine rock or ore-grade materials was based on gold content.
"Other" lithology refers to the following minor lithologies: Metasediment 1, Ultramafic, Calcite Vein, Intrusive Breccia, Felsic Fragmental, Rhyolite, and Sericite Schist.

(1) Total S measured by Leco furnace; Sulphate S measured by HCl cold leach, Sulphide S calculated by difference (Total S - Sulphate S).
(2) Acid Potential calculated as 31.25*Sulphide S; Maximum Acid Potential calculated as 31.25*Total S.
(3) Neutralization Potential measured by Modified Sobeck Method.
(4) Total Carbon measured by Leco furance; TIC measured by HCl leach and Leco furnance; TIC as %C measured by HCl leach.
(5) Carbonate Neutralization Potential calculated from TIC.
(6) Neutralization Potential Ratio calculated as NP/AP; Carbonate Neutralization Potential Ratio calculated as CarbNP/MPA.
Classification as mine rock or ore-grade materials was based on gold content.
"Other" lithology refers to the following minor lithologies: Metasediment 1, Ultramafic, Calcite Vein, Intrusive Breccia, Felsic Fragmental, Rhyolite, and Sericite Schist.

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

Table B-5 Aqua Regia Metals

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

(1) Ten times average crustal abundance values presented in Price (1997).

Blue highlighting indicates samples with metal concentrations greater than the ten times crustal abundance screening value are present in the analyzed group.

Screening values are for qualitative assessment only and hold no regulatory significance.

Classification as mine rock or ore-grade materials was based on gold content.

A value of "--" indicates metal was not measured for the given sample; the variation in elements analyzed is due to measurement at two different laboratories (see text).

Table B-5 Aqua Regia Metals

Sample ID	Drillhole ID	From	To	Lithology	Area	Class	Copper	Iron	Gallium	Germanium	Mercury	Potassium	Lanthanum	Lithium	Magnesium	Manganese	Molybdenum
		m	m				ppm	%	ppm	ppm	ppm	%	ppm	ppm	%	ppm	ppm
10x Crustal Abundance (Price 1997) [(1)]							*600*	*--*	*190*	*15*	*0.85*	*--*	*390*	*200*	*--*	*9500*	*12*
